laminin-332, collagens IV and VII show a broad and branched deposition in the upper dermis. This constellation is highly suggestive of the diagnosis of KS. IF with antibodies to kindlin-1 delivers variable results, including positive, reduced or absent staining, and is therefore not always conclusive.

TEM indicates the level of skin cleavage and reveals the ultrastructure of desmosomes, keratin filaments, hemidesmosomes, anchoring filaments and anchoring fibrils. It is particularly useful in the recognition of EBS Dowling-Meara characterized by clumped keratin filaments and of the KS characterized by reduplications of the lamina densa and multiple levels of cleavage (1).

Depending on the availability of technical equipment and proficient expertise (1,75), either IF or TEM can be employed for EB diagnostics. However, the IF is faster and less costly, and a comparative study showed it to be more sensitive and more specific than TEM in the diagnosis of EB (77).

## 147.6 MOLECULAR GENETICS OF EPIDERMOLYSIS BULLOSA

### 147.6.1 Complexity of the Cutaneous Basement Membrane Zone

Critical for understanding the molecular basis of EB is the recognition of attachment complexes at the dermo-epidermal junction required for stable association of epidermis to the underlying dermis. As indicated earlier in this chapter, initial ultrastructural studies demonstrated the presence of hemidesmosome-anchoring filament complexes that are required for stable association of the basal keratinocytes to the lamina lucida of the underlying basement membrane. Similarly, on the dermal side of the basement membrane zone, there are prominent structures—anchoring fibrils—which secure the association of the lower part of the lamina densa to the upper papillary dermis. Thus, there is a network

**FIGURE 147-12** Clinical features of different EB forms can be very similar in newborn and infants. For example, aplasia cutis may occur in almost any EB form. (A) EBS; (B) JEB-non-Herlitz; (C) JEB-Herlitz; (D) RDEB.

**TABLE 147-3 Differential Diagnosis of EB: Other Genetic Skin Diseases**

Disease	Mutated Genes
Acral peeling skin syndrome <sup>a</sup>	<i>TGM5</i>
Keratinopathic ichthyosis <sup>a</sup>

AEC syndrome <sup>a</sup>	<i>p63</i>
Hailey–Hailey disease	<i>ATP2C1</i>
Darier disease	<i>ATP2A2</i>

<sup>a</sup>In newborn.

structure which extends from the intracellular milieu of basal keratinocytes through the dermo-epidermal basement membrane to the upper papillary dermis. Such an intact network is required for a stable association of the two principal layers of the skin, the epidermis and the dermis, with the intervening basement membrane. Perturbation of this network structure through genetic mutations which lead to the absence of one of the structural components of these attachment complexes, or which perturb critical protein–protein interactions within these complexes, was initially predicted to result in fragility of the skin, in a manner that exposure to minor trauma results in blisters and erosions, characteristic of EB (78).

## 147.6.2 Candidate Genes and Mutation Analysis

Identification and characterization of the genes encoding the structural components of the dermo-epidermal attachment complexes, coupled with immunohistochemical characterization of the corresponding proteins, reveal that hemidesmosomes are composed of proteins encoded by four distinct genes (*COL17A1*, *ITGA6*, *ITGB4*, and *PLEC*) encoding type XVII collagen,  $\alpha 6\beta 4$  integrin, and plectin, respectively. These hemidesmosomal complexes interact with basal cell specific keratin intermediate filaments consisting of keratins 5 and 14, encoded by *KRT5* and *KRT14*. The anchoring filaments traversing the lamina lucida consist primarily of laminin-332 (previously known as laminin 5), a trimeric protein complex comprised of  $\alpha 3$ ,  $\beta 3$  and  $\gamma 2$  subunits encoded by the corresponding genes, *LAMA3*, *LAMB3* and *LAMC2*. Finally, the anchoring fibrils consist predominantly, if not exclusively of type VII collagen encoded by *COL7A1*. Thus, there are 10 distinct candidate genes which can possibly harbor mutations in the classic forms of EB. Subsequently, mutations in these 10 different genes have been identified in different forms of EB, and a large number of mutations have now been identified in different families (55,65). More recently, a consensus panel (1) concluded that three additional clinical conditions displaying fragility of the skin with blistering tendencies should be included in the epidermolysis bullosa diagnostic category. These include lethal acantholytic EB with suprabasal blistering, the KS with mixed level of tissue separation, and ectodermal dysplasia-skin fragility syndrome, with suprabasal tissue separation.

IF, immunofluorescence; TEM, transmission electron microscopy.

These three conditions have been shown to harbor defects in the *DSP*/desmoplakin, *FERMT1*/kindlin-1, and *PKP1*/plakophilin 1 gene/protein systems (see Clinical Features section). An additional case study suggested that a previously unrecognized autosomal recessive form of EBS is caused by mutations in the *DST* gene encoding the epithelial isoform of the 230-kD bullous pemphigoid antigen (BPAG1-e) (47). Finally, lack of plakoglobin as a result of homozygous nonsense mutation in the *JUP* gene was shown to lead to lethal congenital EB (31).

Thus, collectively, there are as many as 16 genes that can harbor mutations in different variants of EB (79). The location of the gene products within the cutaneous basement membrane zone, the types and combinations of mutations, and the consequences of the mutations at the mRNA and protein levels explain the existence of different variants. Furthermore, this genetic heterogeneity, when placed on the individual's genetic background and exposure to external trauma provides an explanation for the considerable phenotypic variability even within a family with the same mutations.

### 147.6.3 Implications of Molecular Genetics for the Management of EB

**147.6.3.1 Genetic Counseling.** Identification of mutations in distinct genes in different variants of EB has made a significant impact on the management of patients with EB through improved diagnosis and subclassification with prognostic implications. Specifically, examination of the mutations in the candidate genes in a newborn can predict, in general terms, the overall prognosis of the affected individual. For example, stop codon mutations in both alleles of the type VII collagen

gene predict a severe phenotype characterized by extensive mutilating scarring and development of aggressive, rapidly metastasizing squamous cell carcinomas. In contrast, the presence of a glycine substitution missense mutation in one allele is likely to result in a significantly milder form of dystrophic form of EB with essentially normal lifespan but with lifelong blistering tendency (65).

Identification of the mutations in a newborn can also have profound consequences for genetic counseling concerning the risk of recurrence in the same or subsequent generations in families with no prior history of EB. This information is particularly useful in the dystrophic forms of EB that can be inherited either in an autosomal dominant or autosomal recessive pattern, occasionally with clinically indistinguishable phenotypes (80).

**147.6.3.2 Prenatal Diagnosis of EB.** Identification of the genes and specific mutations has made a major impact on prenatal testing for EB in families at risk for recurrence. Early on, prenatal diagnosis was based on fetal skin biopsy which required invasive procedures during the latter part of the second trimester, around 17–20 weeks gestation. The interpretation of the fetal skin biopsy by immunohistochemical evaluation or by ultrastructural analysis also required special expertise and personnel that was available only in a few centers globally. DNA-based testing from chorionic villus sampling is now readily available as early as the 10th week of gestation, or from amniocentesis at around 15 weeks (81,82). This testing can be based on either direct mutation analysis or genetic linkage utilizing informative markers within the flanking candidate genes. Such early DNA-based prenatal testing is now in routine use and available in research laboratories or in commercial gene testing laboratories (Table 147-4).

In order to avoid the complications of invasive procedures, including the risk of fetal loss, in chorionic vilus sampling or in amniocentesis, new approaches for prenatal testing from maternal blood have recently been developed. These are based on previous demonstrations of fetal cells and free fetal DNA in maternal circulation (83). Regarding the use of fetal cells as a source of DNA in maternal blood, the estimates of the number of such cells vary widely. It has been estimated, however, based on Y-chromosome specific markers, that there are 2–6 fetal cells per ml of maternal blood in mid-gestation. A number of different cell types have been identified, including trophoblasts, mesenchymal stem cells, nucleated erythrocytes (CD71<sup>+</sup>), and hematopoietic progenitor cells (CD34<sup>+</sup>). These cell populations can be enriched by different techniques, including flowcytometry, magnetic bead separation, density-gradient centrifugation and laser capture microscopy. While the use of fetal cells isolated from the maternal blood for prenatal diagnosis is still being developed, a significant concern relates to the fact that fetal cells can persist in maternal tissues for years after pregnancy (84). This would complicate the use of this technique in subsequent pregnancies. However, prenatal diagnosis for predicting the fetal genotype from fetal cells in maternal circulation has been successful in case of a number of diseases, including  $\beta$ -thalassemia, sickle cell anemia, and lamellar ichthyosis (83).

The maternal plasma also contains free fetal DNA that is easily detectable by PCR (85,86). The concentration of fetal DNA in maternal blood progressively increases during pregnancy, and it accounts for ~3–6% of total free DNA at term. This DNA is likely a reflection of trophoblast breakdown, as fetal free RNA, which has been shown to be placentally derived, can also be detected in maternal blood (87). The advantage of assaying the free fetal DNA in plasma is that it disappears very rapidly after the birth, and at 24 h post-partum very little, if any, fetal DNA can be detected. A limitation of prenatal testing by analysis of fetal free DNA in maternal circulation relates to the fact that the maternal allele in fetal DNA is masked by maternal DNA. Thus, the feasibility of utilizing this approach is limited to screening for a paternal allele of a paternally-derived dominant mutation or in compound heterozygotes. Nevertheless, this approach has been successfully used for prenatal diagnosis of cystic fibrosis, achondroplasia, congenital adrenal hyperplasia, and other conditions. Furthermore, the fetal *RHD* gene locus in rhesus negative mothers can be analyzed by this approach (83).

**147.6.3.3 Preimplantation Genetic Diagnosis.** An extension of DNA-based prenatal testing, preimplantation genetic diagnosis, can now be performed in connection with in vitro fertilization. This technology has advantages in terms of avoiding the ethical issues related to the termination of a pregnancy, if elected, but its utility has been somewhat limited by relatively low success of in vitro fertilization procedures in general, and the costs of this procedure. Nevertheless, the feasibility

of this approach has already demonstrated in case of patients with EB (88,89).

## 147.7 TREATMENT AND THERAPEUTICS

### 147.7.1 Prevention and Wound Care

So far, no cure exists for EB, and the treatment is primarily supportive and symptomatic. The best practice encompasses protection from mechanical friction and trauma, combined with meticulous wound management and skin care. Strongly adhesive bandages should not be used, since they cause blistering in all EB subtypes. New blisters should be opened to reduce fluid pressure, but the blister roof not removed; it acts as a protective layer during re-epithelialization. Wound care consists of cleansing and application of appropriate non-adhesive dressings, such as hydroactive colloid gels or silicon-based dressings (90). Crèmes that further re-epithelialization are useful, and topical corticosteroids may reduce itch caused by secondary eczematization. Topical antibiotics are required for the treatment of secondary infections. In general, the wound management should aim at reducing pain and complications, such as infection, and at enhancing quality of life. In severe forms of EB, the secondary involvement of many other organs requires multi-disciplinary management in specialized centers.

### 147.7.2 Development of Molecular Therapies for EB

Not until very recently, there has been relatively little progress in developing effective and specific treatments for EB. However, identification of specific mutations in the candidate genes and elucidation of the consequences of such mutations have provided a basis for development of novel therapeutic approaches, taking advantage of the progress in molecular and cell biology in general areas. These approaches consist of gene therapy, protein replacements, or cell based therapies (79). Some of these approaches, such as allogeneic bone marrow transfer and fibroblast therapy, are in early clinical trials for patients with RDEB (91,92).

## 147.8 REVERTANT MOSAICISM

Revertant mosaicism is a naturally occurring phenomenon involving spontaneous correction of a pathogenic mutation in a somatic cell, and this has been described in different forms of EB, particularly in junctional, due to *COL17A1* mutations (93,94). Clinically, revertant mosaicism manifests with patches of normal appearing, nonblistering skin (see Figure 147-13). Besides providing a useful model system to study revertant mosaicism in general, revertant mosaicism may provide an opportunity for autologous cell therapy through propagation of keratinocytes from the revertant area. These cells can

**FIGURE 147-13** Revertant mosaicism in EB. (A) Normal appearing skin areas (outlined with black) surrounded by affected skin with erosions and scars in a patient with RDEB. (B) If staining with antibodies to collagen VII (green) of a control skin sample (left), a skin sample from a patient with severe generalized RDEB (middle), and biopsy from a revertant area of skin of the same patient (right). Nuclei are stained in blue with DAPI; bar = 50  $\mu$ m (Courtesy of Dr Dimitra Kirts, Freiburg).

then be incorporated into epithelial sheets, with subsequent grafting to the blistered and eroded areas (95).

### 147.9 ANIMAL MODELS

The value of animal models in advancing our understanding of the disease mechanisms in EB has been amply demonstrated by the development of genetically modified mice that recapitulate features of different forms of this disease (96). In addition, a number of naturally occurring mutations resulting in blistering phenotypes in larger animals, such as dogs, sheep, and horses, have been identified (97). These animal models serve now as a platform to develop molecular therapies for EB.

### 147.10 THE ROLE OF PATIENT ADVOCACY ORGANIZATIONS

Disease-specific advocacy organizations (also known as “support groups”), provide support and education to affected individuals and their families regarding their disease, its treatment, and the latest developments in research (98). These organizations are increasingly becoming involved in research through fund raising and grant support, as well as soliciting patients for clinical trials (99). The premiere patient advocacy organization for EB is the Dystrophic Epidermolysis Bullosa Research Association (DebRA) International, a network

### Biographies

**Cristina Has, MD**, studied medicine from 1985 to 1991 at the Medical University Cluj-Napoca, Romania. She received her MD degree, and completed her residency training in dermatology at the same university. She continued her postdoctoral work in genetics at the University of Münster, Germany and the National Center of Genotyping Evry, France. In 2003, Dr Has joined Dr Bruckner-Tuderman in the Department of Dermatology, managing the molecular genetic diagnosis of EB, and became Professor in 2012. Dr Has has experience in genetic testing for a number of inherited diseases, and is the author of numerous scientific articles on the genetics of EB and other genodermatoses. Her clinical and scientific specialties are blistering skin diseases, genodermatoses and molecular genetics of the skin.

**Leena Bruckner-Tuderman, MD**, has been Professor and Chair of the Department of Dermatology at the University Freiburg Medical Center in Freiburg, Germany since 2003. She studied medicine in Oulu, Finland, and after an experimental dissertation in molecular medicine, continued her postdoctoral work in biochemistry in Piscataway, NJ, USA, and in structural biology in Basel, Switzerland. She specialized in dermatology at the University of Zurich, Switzerland. She has held prestigious fellowships in Switzerland and Germany and has been Visiting Professor at the University of Hong Kong and at Harvard Medical School, Boston. The internationally recognized research of Leena Bruckner-Tuderman focuses on molecular genetics and disease mechanisms of skin fragility syndromes, biology of basement membranes and the extracellular matrix, epithelial-mesenchymal communication, and cell-matrix interactions, and more recently on development of cell-, gene- and protein-based therapies. Her publications include more than 300 original articles in peer-reviewed journals. Since 2007 Dr Bruckner-Tuderman has been a fellow and director of the School of Life Sciences–LifeNet of the Freiburg Institute for Advanced Studies, FRIAS and since 2009 she has been a founding member and one of the directors of Freiburg Center for Rare Diseases. She is a board member of many national and international foundations, programs, committees and editorial boards for journals in dermatology and venerology, as well as a member of the German Academy of Sciences Leopoldina, and a scientific advisor to the German Research Foundation DFG and the Federal Ministry for Education and Research, BMBF.

**Jouni Uitto, MD, PhD**, has been Professor of Dermatology and Cutaneous Biology, and Biochemistry and Molecular Biology, and Chair of the Department of Dermatology and Cutaneous Biology at Jefferson Medical College, in Philadelphia, Pennsylvania, since 1986. He is also Director of the Jefferson Institute of Molecular Medicine at Thomas Jefferson University. He received his MD and PhD degrees from the University of Helsinki, Finland, and completed his residency training in dermatology at Washington University School of Medicine, St. Louis, Missouri.

Dr Uitto is internationally recognized for his research on connective tissue biology and molecular genetics in relation to cutaneous diseases. Dr Uitto's publications include 623 original articles in peer-reviewed journals, 298 textbook chapters and review articles, and 920 abstracts on presentations in national and international meetings (7/2011). Dr Uitto has been the recipient of numerous national and international awards, including Honorary Doctoral degrees from the University of Kuopio, University of Oulu and University of Turku, all in Finland, as well as Honorary Professorship at China Medical University, Shenyang.

Dr Uitto has held office in several scientific and professional societies, including President of the Society for Investigative Dermatology; and President and Chairman of the Board of Trustees of Dermatology Foundation. Dr Uitto is also section editor of the *Journal of Investigative Dermatology*, associate editor of the *American Journal of Pathology*, and he is on the editorial boards of numerous peer-reviewed journals.

### GLOSSARY

#### Ankyloblepharon

**Pronunciation** – āng'kə-lō-blēf'ə-rŏn'

**Function** – noun

**Definition** – Adhesion of the eyelids to each other; also called blepharosynechia

#### Eccrine

**Pronunciation** – ěk'rĭn

**Function** – adjective

**Definition** – of or pertaining to certain sweat glands, distributed over the entire body, which secrete a type of sweat important for regulating body heat

#### Ectoderm

**Pronunciation** – ek-tuh-durm

**Function** – noun

**Definition** – The outer germ layer of an animal embryo, which gives rise to epidermis and nervous tissue

#### Hypodontia

**Pronunciation** – hĭ'pō-dŏn'shē-ə, -shə

**Function** – noun

**Definition** – A congenital condition of having fewer than the normal number of teeth.

#### Hypohidrosis

**Pronunciation** – hĭ'pō-hĭ-drō'sĭs

**Function** – noun

**Definition** – Abnormally diminished sweating

#### Hypotrichosis

**Pronunciation** – hĭ'pō-trĭ-kō'sĭs

**Function** – noun

**Definition** – A less than normal amount of hair on the head or body.

is generally accepted that two or more systems must be affected in order for a condition to be defined as an ectodermal dysplasia syndrome. The ectodermal dysplasia syndromes may be associated with defects of additional organ systems as well. The mammary gland, thyroid gland, adrenal medulla, anterior pituitary, central nervous system, external ear, cornea, conjunctiva, lacrimal gland and lacrimal duct are other structures that are derived from the embryonic ectoderm. Congenital malformations of teeth, hair, nails, or sweat glands may also occur as single isolated malformations. Developmental disorders involving only one type of structure (teeth, hair, nails, or sweat glands), even if associated with other malformations, have arbitrarily been classified as not constituting an ectodermal dysplasia syndrome.

Almost 200 conditions have been classified as ectodermal dysplasias (1). Various classification schemes have been proposed over the past 30 years. Freire-Maia and Pinheiro published a monograph in 1984 (with later updates) that classified the disorders according to clinical features and associated defects (2–4). They divided the ectodermal dysplasias into groups, based on which of the basic ectodermal structures of hair, teeth, nails, or eccrine sweat glands were involved. Group A conditions had at least two ectodermal structures affected, while group B conditions had only one of the four major ectodermal structures involved, but had other ectodermal defects of the ears, lips, palms or soles. All possible combinations of two or more structures were described, resulting in 11 subgroups. However, the investigators realized that this taxonomic system is arbitrary, and did not take into account the pathogenesis or genetics of the specific disorders. Identification of the genes responsible for some of these disorders in humans and other animals, and the understanding of the developmental biology of such structures as hair, skin and teeth have advanced markedly during the past 15 years (5–7). These scientific advances have led to efforts to reclassify the ectodermal dysplasias on basis of molecular and developmental biology (8–13).

### 148.1 INTRODUCTION

The ectodermal dysplasias are a complex and heterogeneous group of disorders characterized by anomalies of ectodermal structures, including abnormalities of the teeth, hair, nails, sweat glands or other eccrine glands. These malformations result from developmental defects in tissues in which progenitor cells were originally derived from the ectoderm of the developing embryo. It

The ectodermal dysplasias can be grouped according to their molecular basis, including the categories of defects in the NF- $\kappa$ B signaling pathway genes, transcription factors, gap junctions, structural molecules and adhesive molecules. The development of epithelial appendages depends on intricate networks mediating epithelial–mesenchymal interactions during development. Genetic studies of the ectodermal dysplasias have helped define these networks, and have led to the elucidation of developmental pathways. Hopefully, these scientific discoveries will lead to molecularly-based therapies, with the possibility of treating or replacing defective and missing teeth, hair follicles, or eccrine sweat glands. In the future, new tissue engineering techniques using adult stem cells may be able to treat hypodontia postnatally (14). Gene delivery and therapy to existing hair follicles and skin is also being actively explored (15,16). Finally, even in utero therapy may be possible in the future to replace deficient proteins or genes needed for normal development. This has recently been done for the X-linked form of hypohidrotic ectodermal dysplasia in the *tabby* mouse (17).

All of the ectodermal dysplasias appear to be genetic in etiology, with every mode of Mendelian inheritance encountered among the syndromes. The actual number of distinct, non-allelic disorders is unclear. Although almost 200 conditions have been described, many have been reported in only one or two families, and there is

often significant clinical overlap among the conditions. Ultimately, a full understanding of the basic defects in these disorders will help determine how many individual disorders exist. Already a number of separately classified ectodermal dysplasia syndromes associated with orofacial clefting have been shown to be allelic and due to p63 mutations. There are no accurate population-based studies of the prevalence of this group of disorders. The most common condition among the ectodermal dysplasias is hypohidrotic ectodermal dysplasia. Individuals with this disorder, usually inherited as an X-linked recessive trait, account for 80% of families registered with the National Foundation for Ectodermal Dysplasias, an organization for families with individuals affected with ectodermal dysplasia in the United States. Various other ectodermal dysplasia syndromes account for the remaining membership, including ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome and other p63-related conditions, Clouston syndrome (hidrotic ectodermal dysplasia), incontinentia pigmenti, tricho–dento–osseous syndrome, Goltz syndrome and Witkop (tooth and nail) syndrome. A discussion of all of the ectodermal dysplasias is beyond the scope of this chapter, but the most common and classic ectodermal dysplasia syndromes are reviewed, with a discussion of their clinical features, genetics, diagnosis, and management. (See summary in Table 148-1.)

**TABLE 148-1 Genes and Chromosomal Regions for Selected Ectodermal Dysplasias**

Chromosome	Gene	Protein or Gene Product	Inheritance	Ectodermal Dysplasia (ED)	Protein Function	OMIM Number

## 148.2 HYPOHIDROTIC ECTODERMAL DYSPLASIA

### 148.2.1 Clinical Features

X-linked hypohidrotic ectodermal dysplasia (XLHED), also known as anhidrotic ectodermal dysplasia or Christ–Siemens–Touraine syndrome (MIM 305100), is the most common ectodermal dysplasia syndrome. The majority of individuals with hypohidrotic ectodermal dysplasia have the X-linked form. It is characterized by hypotrichosis (sparseness of scalp and body hair), hypohidrosis (reduced ability to sweat), and hypodontia (congenital absence of teeth). This condition was first recognized by Dr John Thurnam in 1848 in two male cousins. In 1875, Charles Darwin discussed it in “The variation of animals and plants under domestication” (2nd ed.), saying:

*I may give an analogous case, communicated to me by Mr. W. Wedderburn, of a Hindu family in Scinde, in which ten men, in the course of four generations, were furnished, in both jaws taken together, with only four small and weak incisor teeth and with eight posterior molars. The men thus affected have very little hair on the body, and become bald early in life. They also suffer much during hot weather from excessive dryness of the*

*skin. It is remarkable that no instance has occurred of a daughter being thus affected.*

The gene was assigned to the X chromosome in 1921 by Thadani. In 1929, Weech reported additional cases and expanded the clinical description. Subsequently, it has been determined that, in addition to the common X-linked form of HED due to mutations in the EDA1 gene (XLHED), there are clinically indistinguishable autosomal recessive forms (ARHED) (MIM 224900) and milder autosomal dominant forms (ADHED) (MIM 129490) due to mutations in the EDAR and EDAR-ADD genes (18,19). The exact prevalence of HED is not known, but it is estimated that at least one in 5000–10,000 newborns has the disorder.

The majority of affected males with XLHED and males and females with ARHED have significant dental abnormalities. They have hypodontia and are missing most of their primary and secondary dentition. Occasionally, there may be complete anodontia. Nine permanent teeth are present on average (20). The central incisors and canines may have a conical or peg shape (Figure 148-1) and the molars may have hooked cusps. The alveolar ridges are noticeably hypoplastic, which can be a clue to absence of the underlying dentition in infants and young children.

There is hypotrichosis (Figure 148-2), with sparse scalp hair in childhood and subsequent premature balding in adolescents and adults. The hair tends to be hypopigmented, fine and short. There may be slow growth and excessive breakage of the hair shafts. Body hair and eyebrows are also sparse, and eyelashes may be thin to absent. However, beard and mustache hair are near normal in adults, and axillary and pubic hair may be present.

**FIGURE 148-1** Boy with XLHED showing conical teeth and sparse hair and eyebrows.

**FIGURE 148-2** Boy with XLHED.

Variable degrees of hypohidrosis are present, and significant episodes of hyperthermia frequently occur in infancy and early childhood. The eccrine sweat glands are sparse to absent, while apocrine glands are more normal. Sebaceous glands are also hypoplastic to absent. The skin is generally smooth, dry and soft and appears fragile. There are fine wrinkles around the eyes with persistent periorbital hyperpigmentation. Affected individuals are also susceptible to eczema and atopic dermatitis. There may be mild nail dystrophy, but it is less significant than in other forms of ectodermal dysplasia. There is often lack of dermal ridges.

The craniofacial appearance is distinctive, with frontal bossing, prominent supraorbital ridges, short nose with depressed nasal bridge (saddle nose), small alae nasi, maxillary hypoplasia, full lips and mild prognathism (Figures 148-3 and 148-4). The ears may be prominent. There is absence of tear production due to involvement of lacrimal glands. There is also a hoarse or raspy voice. Abnormal development of the nasal and respiratory mucosal glands leads to frequent respiratory infections in early childhood. Atrophic rhinitis with ozena (foul-smelling nasal discharge) and nasal concretions (solidified secretions in the nasal air passages) are problematic throughout life. Physical growth and psychomotor development are usually normal. Some individuals have difficulty gaining weight in infancy and early childhood, and maintain a thin body habitus.

**FIGURE 148-3** Boy with XLHED.

Although some affected individuals may have extensive peeling of the skin as newborns, most babies appear normal at birth, creating difficulties in the early diagnosis of the disorder. If the disorder is unrecognized, it can cause morbidity and even mortality (ranging from 2 to 20% based on varying reports) during infancy and early childhood, mainly due to the neurologic sequelae of unrecognized episodes of hyperthermia (21). Febrile seizures may occur in 5.9% of infants with XLHED and 17% of infants with other forms of HED. The diagnosis of HED is usually delayed until the teeth fail to erupt on time, or the teeth that do appear are noted to have an abnormal conical shape.

Female carriers of XLHED can have a broad range of clinical involvement; some may appear completely normal, while others may exhibit any or all of the characteristic features, including clinically significant hypodontia, hypotrichosis, and unilateral or bilateral hypoplasia of the breasts with deficient milk production during lactation. They may have patchy distribution of sweat function. In families with no affected males, on the basis of chance alone, there may be one or more manifesting female carriers, which can cause difficulties in diagnosis. Many mildly affected females are not diagnosed with the disorder until after a fully affected male is born in their family. The wide clinical variability seen in carrier females is due to the process of X-inactivation (Lyonization), and significantly complicates carrier detection based on physical examination. Female carriers of XLHED are mosaics of functionally normal and abnormal cells, with their clinical findings dependent on the percentage of abnormal cells in the progenitor cells that gave rise to their hair, teeth, and glands. Rarely, fully affected females may be observed due to a balanced X;autosome translocation,

**FIGURE 148-4** Girl with HED showing characteristic facies and sparse hair.

chromosomal aneuploidy (such as coexisting Turner syndrome), or extreme skewing in random X-inactivation. Males and females with ADHED typically have milder features of HED.

### 148.2.2 Genetics

XLHED is caused by mutations in the gene for ectodysplasin (EDA). The initial clue to location of the HED locus on the X chromosome came from the description of a female patient with complete manifestations of HED and an apparently balanced chromosomal rearrangement between one of her X chromosomes and chromosome 9. At least three other affected females with X;autosome balanced translocations have been identified, all with breakpoints in the Xq12–q13.1 region. Genetic mapping studies using linkage analysis confirmed the localization of the gene to the Xq12–q13.1 region. Positional cloning of the EDA gene was accomplished by identification of closely linked markers flanking the locus. The isoform of the gene isolated initially contained only two exons, and mutations were found in only 10% of affected individuals. However, the subsequent isolation of additional isoforms led to the identification of mutations in 95% of XLHED families. The active ectodysplasin isoform (EDA-A1) encodes a 135 amino acid protein, with a single transmembrane domain, and includes a collagen-like domain within the extracellular region. The protein is a member of the tumor necrosis factor (TNF) ligand super-family. The protein is expressed in the epithelial cells of developing skin and hair follicles. Ectodysplasin is the ligand in a developmental signaling pathway named the EDA signal transduction pathway (Figure 148-5) (22).

Mutations at three separate loci within the EDA pathway are responsible for clinically indistinguishable forms of hypohidrotic ectodermal dysplasia. The pathway consists of a ligand, ectodysplasin, its receptor (EDAR), and a receptor associated intracellular protein (EDARADD). The receptor complex transduces a signal to the nucleus by means of the NF- $\kappa$ B transcription factor, which ultimately leads to the appropriate cellular response (23). The ectodysplasin pathway shares several common downstream elements (NF- $\kappa$ B, IKK complex) with other TNF signal transduction pathways (24). Understanding of the role of the ectodysplasin pathway in both tooth and hair follicle development has been aided by experiments in wild-type and mutant mice (25–27). Of great potential future therapeutic importance in humans, treatment of pregnant *tabby* mice with a recombinant form of EDA1 engineered to cross the placental barrier permanently rescued the *tabby* phenotype in the offspring (17). Treatment of *tabby* mice and dogs with XLHED within days after birth with recombinant ectodysplasin has also been

**FIGURE 148-5** Ectodysplasin signal transduction pathway. (Adapted from Mikkola, M. L. *Molecular Aspects of Hypohidrotic Ectodermal Dysplasia*. Am. J. Med. Genet. A. **2009**, 149A (9), 2031–2036.)

shown to correct many of the symptoms of the disorder (17,28). The gene for the *downless* locus in the mouse was found to be the receptor (EDAR) for the EDA-A1 ligand. Mutations within the human homolog are responsible for both ARHED, and the milder ADHED (29) (Figure 148-6). Missense mutations within different domains of the receptor can result in different patterns of inheritance for the disorder. Missense mutations within the extracellular ligand-binding domain (C87R; R89H) cause autosomal recessive hypohidrotic ectodermal dysplasia. The mutations abolished or severely diminished EDAR *in vitro* binding to EDA-A1 (30). Other mutations in EDAR have also been identified (18). An even rarer autosomal recessive disorder also produces an identical phenotype to XLHED, and mutations have been found in *crinkled* mice and humans in an adaptor protein (EDARADD) that interacts with the EDAR receptor (31,32). The ectodysplasin pathway regulates NF- $\kappa$ B signaling through a key regulatory protein IKK-gamma (IKBKG, previously known as NEMO). Hypomorphic mutations affecting IKBKG function cause a closely related disorder hypohidrotic ectodermal deficiency with immunodeficiency (HED-ID) (33) (see further discussion below). Complete loss of function of IKBKG causes prenatal lethality in affected males, and causes the allelic disorder incontinentia pigmenti in females (34).

**FIGURE 148-6** Boy with autosomal recessive HED due to mutations in the EDAR gene. (With permission from Naeem, M.; Muhammad, D.; Ahmad, W. *Novel Mutations in the EDAR Gene in Two Pakistani Consanguineous Families with Autosomal Recessive Hypohidrotic Ectodermal Dysplasia*. *Br. J. Dermatol.* **2005**, 153 (1), 46–50.)

### 148.2.3 Diagnosis and Differential Diagnosis

X-linked hypohidrotic ectodermal dysplasia can be identified beyond infancy by physical signs and symptoms. The issue of genetic heterogeneity is important because, as noted previously, rare autosomal recessive and dominant forms of hypohidrotic ED, as well as HED-ID must be considered in the differential diagnosis. If families have only a single affected male individual or sibship,

autosomal recessive inheritance cannot be distinguished from X-linked recessive inheritance. The risk of having an affected male in the offspring of aunts, sisters, and daughters of an affected individual would be negligible if the condition in the particular family is inherited as an autosomal recessive trait, but may be as high as 25% if the trait is X-linked. It appears that the majority of families with hypohidrotic ectodermal dysplasia have mutations in the EDA1 gene located at Xq12–q13.1. However, the possibility of genetic heterogeneity should be included in the genetic counseling of families when only a single individual or sibship is affected, especially families with consanguinity or those with fully affected females. Fully affected females should have a karyotype performed to rule out an X;autosome translocation. If there is a history of significant or recurrent infections in a male with HED, the related disorder of hypohidrotic ectodermal dysplasia with immunodeficiency (HED-ID) due to IKBKG mutations must be considered (see further discussion below).

Clinical tests were developed in the past to help identify carrier females on the basis of dental and sweat pore analyses, but most had significant limitations in administration and subjective interpretation, as well as overlap of the findings between the normal and carrier populations. Diagnostic mutation analysis of the EDA gene can overcome the problems presented by the phenomenon of lyonization in carrier testing.

Molecular testing can help distinguish the different types of HED, and assist in determining whether females are carriers of XLHED. Direct mutation analysis of EDA is clinically available for the X-linked form, including sequencing of the EDA gene as well as deletion analysis. The EDA gene would usually be analyzed first, unless autosomal recessive inheritance was suggested by the presence of a severely affected female or consanguinity within the pedigree. Several groups, surveying over 100 patients with presumed XLHED, have identified numerous EDA mutations (30,35,36). Mutation detection rates varied from 63% to 95%, due to the detection methods utilized and patient selection. Mutation detection rates were higher in typically affected male patients, and in families with more than one affected generation. There are a few recurrent mutations, especially in codons 155 and 156, and specifically the R156H mutation, but many families have private mutations. Deletions are identified in at least 10% of cases. Clinical molecular testing of the receptor (EDAR) is also available for families with possible autosomal recessive or dominant forms of the disorder. EDARADD mutations have only been described in a few families, and clinical testing for this form of the disorder is not yet available. As with most clinical molecular testing, inability to find a mutation in a family reduces the probability that the family has a specific form of HED, but does not eliminate it.

### 148.2.4 Management and Counseling

There is intrafamilial and interfamilial variability in the degree of hypohidrosis and hypodontia. The identification of affected individuals at an early age is extremely important to avoid episodes of uncontrolled hyperthermia due to the inability to sweat, and to prevent potential central nervous system damage or even death. Hot environments and fevers must be managed with cooling measures or antipyretics. Affected individuals must have access to an adequate supply of water and a cool environment. Wearing a “cooling vest” or a wet T-shirt and using a spray bottle of water when outdoors can help maintain a cool body temperature. With appropriate measures, normal life expectancy and intelligence can be achieved. Dry skin and eczema are seen in most affected individuals and require skin care products and possibly dermatological consultation. The nasal mucosa is also involved with problems of crusting and ozena, and this can be treated with the application of nasal solutions. Regular visits with an ENT physician may be necessary to manage the nasal and aural concretions (37). Dental treatment must begin at an early age and is needed throughout childhood, due to the absence of most of the deciduous and permanent dentition. Bonding of the conical shaped teeth in young children may be done to improve the appearance and chewing ability. Hypodontia is treated with dentures beginning early life, as early as three years of age, and dental implants are a treatment option in older individuals (38–40).

Families can benefit from a medical genetic evaluation for both diagnostic and reproductive counseling purposes. Affected individuals may have a prior family history of the disorder, but in many cases there is only a single affected individual representing a new mutation in the gene. Females who carry an EDA gene mutation have a 25% risk of having an affected son and a 25% risk of having a carrier daughter with each pregnancy. Affected males cannot pass the trait on to their sons, but all of their daughters are carriers of the disorder and may show variable clinical expression.

Identification of the carrier status of at-risk females is possible by physical examination in some female carriers, when the findings are unambiguously abnormal, with examination of the dentition being the most reliable approach. Subclinical tests of sweating can be misleading, and subjective assessment of heat intolerance and thin hair should be avoided. Clinical availability of direct mutation analysis allows diagnosis and carrier testing for XLHED. Such testing and counseling of at-risk females would best be deferred until reproductive age.

As with many X-linked disorders, female carriers of EDA mutations may request prenatal diagnosis of the disorder, while others have chosen testing of their newborn males postnatally to see if they are affected. Prenatal diagnosis of EDA or EDAR mutations using direct

DNA-based diagnostic testing is feasible. Pre-implantation genetic diagnosis may be available for families in whom the specific mutations have been identified.

## 148.3 ODONTO-ONYCHO-DERMAL DYSPLASIA (OODD) SYNDROME (MIM 257980)

### 148.3.1 Clinical Features

Odonto-onycho-dermal dysplasia (OODD) syndrome, a form of hypohidrotic ectodermal dysplasia, has been shown to be caused by mutations in the WNT10A (wingless-type MMTV integration site family, member 10A) gene (41). There is a broad spectrum of clinical features in these patients, typically including significant hypodontia as well as abnormal fingernails and toenails (42). Most cases are inherited in an autosomal recessive fashion, associated with homozygous or compound heterozygous WNT10A mutations, but up to 50% of heterozygotes may display some clinical features.

The most consistent clinical feature is severe hypodontia of the permanent teeth. Some patients may have anodontia. The deciduous teeth are often nearly normal in number, but may be small and widely spaced. There may be a smooth tongue with reduced fungiform and filiform papillae. Hair is absent at birth, and older individuals have dry and thin hair and may have sparse eyebrows. When examined by electron microscope, the hair shaft has longitudinal depressions. Skin manifestations include palmar erythema and keratoderma of the palms and soles. Hyperhidrosis involving the palms and soles is commonly present. Some affected individuals may have hypohidrosis and keratosis pilaris elsewhere on the body. Histologically, the skin shows orthokeratosis, hyperkeratosis, hypergranulosis and mild acanthosis in the epidermis. The fingernails and toenails are dystrophic (onychodysplasia) and there can be congenital absence of nails (anonychia).

Schopf-Schulz-Passarge syndrome (SSPS) is a rare disorder characterized by eyelid hidrocystomas (eyelid cysts) in association with other findings of ectodermal dysplasia similar to those seen in the OODD syndrome (43) (Figure 148-7). Recently, this disorder was also shown to be due to mutations in the WNT10A gene (44,45).

### 148.3.2 Genetics

Mutations in the WNT10A gene have been reported in up to 9% of individuals with ectodermal dysplasia and in 25% of individuals with hypohidrotic ectodermal dysplasia who do not have a mutation in the EDA gene (46,47). A recent report indicates that WNT10A mutations may be more common than previously suspected (48). Sixty-five cases of HED were analyzed for mutations in EDA, EDAR, EDARADD and WNT10A; 58% had EDA mutations, 16% had EDAR mutations and 16% had WNT10A mutations for a total detection rate of 90%, and only one

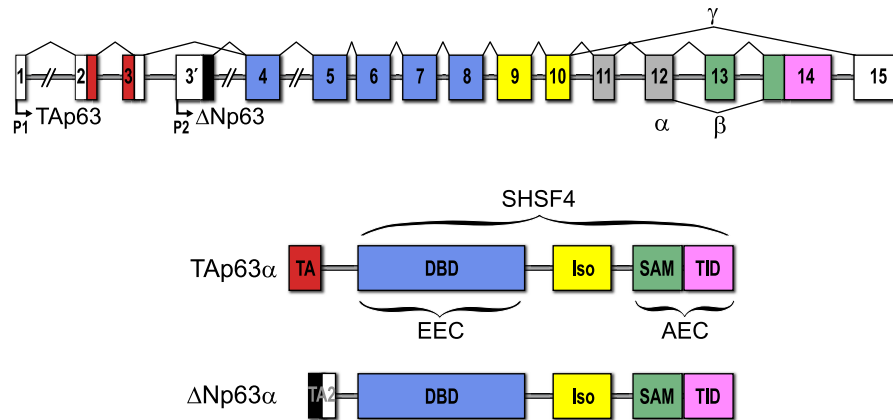

**FIGURE 148-7** Woman with Schopf-Schulz-Passarge syndrome due to WNT10A mutations. (a) Palmo-plantar keratoderma. (b) Sparse, thin scalp hair. (c) Onychodystrophy. (d) Opalescent and translucent cyst-like lesions of the eyelid margins. (e) Telangiectatic rosacea. (f) Dis-seminated milia over the nasal tip and columella. (g) Bilateral hypoplastic nipples. (h) Panoramic radiograph showing severe oligodontia. (With permission from Castori, M., et al. Schopf-Schulz-Passarge Syndrome: Further Delineation of the Phenotype and Genetic Considerations. *Acta Derm. Venereol.* 2008. 88(6): p. 607-612.)

case had an EDARADD mutation (48). Molecular genetic testing is clinically available for WNT10A.

#### 148.4 P63-RELATED ECTODERMAL DYSPLASIA SYNDROMES

There are multiple well-recognized ectodermal dysplasia syndromes that are associated with mutations in the p63 gene (49). These disorders are a heterogeneous group with some overlapping clinical features, but there are also distinctive features that allow them to be separated into different syndromes. The disorders include ectrodactyly-ectodermal

dysplasia-clefting (EEC) syndrome (MIM 604292), ankyloblepharon-ectodermal defects-cleft lip/palate (AEC) or Hay-Wells syndrome (MIM 106260), limb-mammary syndrome (LMS) (MIM 603543), acro-dermato-ungual-lacrimal-tooth (ADULT) syndrome (MIM 103285), Rapp-Hodgkin syndrome (RHS) (MIM 129400) and split hand-split foot malformation (SHFM4) syndrome (MIM 605289). The differences in the phenotypes are linked to the domain of the protein in which the mutation is located. The p63 gene, which is located at 3q27, encodes a transcription factor that has a critical role in epithelial appendage development (50) (Figure 148-8). At least six different

**FIGURE 148-8** p63 gene structure and two of the protein isoforms, indicating the locations of the typical mutations for EEC, AEC and SHFM4 syndromes.

transcripts can be generated by alternative promoter usage and splicing. The protein domains include an amino-transactivating domain, a core DNA-binding domain, a carboxy-oligomerization domain, a sterile alpha motif (SAM) domain and a transactivation inhibitory domain (TID). The DNA binding domain and an oligomerization domain are shared by all isoforms, while only a subset of isoforms has a transactivation inhibitory domain or a SAM domain. The SAM domain is devoted to protein–protein interaction and is implicated in developmental processes. The p63 protein has been shown to be localized to the nuclei of basal cells in stratified epithelium, including the skin, oral mucosa, cervical and vaginal epithelium, urothelium and breast (51,52).

## 148.5 ECTRODACTYLY, ECTODERMAL DYSPLASIA, AND CLEFT LIP/PALATE SYNDROME (MIM 604292)

### 148.5.1 Clinical Features

Ectrodactyly–ectodermal dysplasia–clefing (EEC) syndrome is the most common ectodermal dysplasia syndrome associated with mutations in the p63 gene. In addition to abnormalities of hair, skin and teeth, patients with classic EEC syndrome have cleft lip and palate and ectrodactyly (split hands or feet). There is a characteristic facies with maxillary hypoplasia, a broad nasal tip and a short philtrum (Figure 148-9). The scalp hair is sparse and fine, and there may be patches of alopecia. The eyebrows and eyelashes are sparse as well. The nails may be thin and brittle, or may have pits. Dental abnormalities may include hypodontia, conical-shaped teeth, and enamel dysplasia leading to an increased risk of caries. The skin may be thin and dry resembling dermatitis and with an increased susceptibility to eczema. However, sweating is relatively normal in this condition. The majority of cases have clefting, usually cleft lip and palate, although either isolated cleft lip or isolated cleft palate can be seen. Blepharitis, keratitis, and dacryocystitis due to absent or hypoplastic lacrimal

**FIGURE 148-9** Boy with EEC and repaired cleft lip and palate.

puncta can occur. The characteristic limb defects include ectrodactyly (split hands and feet) and syndactyly, but the presentation is variable (Figure 148-10). All four extremities may be affected, only one or two, or none at all. Central nervous system malformations have been reported in EEC syndrome, with growth hormone deficiency due to hypothalamic–pituitary insufficiency in a few cases, and semilobar holoprosencephaly associated with hypogonadotropic hypogonadism and central diabetes insipidus in another case. Choanal atresia has been reported occasionally. Genitourinary anomalies are frequently found and

**FIGURE 148-10** A and B. EEC feet and hand.

can include hydroureter, hydronephrosis, and renal agenesis. Mental retardation is rare in EEC syndrome. There is significant intrafamilial and interfamilial variability in the associated malformations.

### 148.5.2 Genetics

EEC syndrome has an autosomal dominant inheritance pattern with highly variable expression. EEC syndrome has non-allelic heterogeneity and has been localized to three different loci, EEC1 (MIM 129900), EEC2 (MIM 602077) and EEC3 (MIM 604292), but only the p63 gene at 3q27 has been identified thus far as the molecular basis of EEC3, and p63 mutations are found in 98% of classic EEC syndrome cases (53). EEC1 has been mapped to 7q21 based on translocations and deletions in patients with syndromic split hand and split foot and by linkage analysis (54,55). EEC2 has been mapped to chromosome 19 in one family. The predominant mutations seen in the EEC syndrome are amino acid substitutions in the DNA-binding domain of the protein while mutations in other parts of the protein cause related clinical conditions (56).

### 148.5.3 Management and Counseling

Treatment for EEC syndrome involves surgical correction of the cleft lip and palate, as well as management of any associated speech, dental, or hearing problems. Treatment for lacrimal duct anomalies is also frequently needed. Orthopedic or plastic surgery management of the hand and foot malformations, and occupational therapy intervention, should be employed as needed. Hypodontia can be treated with appropriate prosthodontic care, including dental implants. All patients should be evaluated for clinically significant genitourinary anomalies, and if growth disturbance or any other endocrine abnormality is present, an evaluation of the hypothalamic–pituitary axis would be indicated. In families with a clear clinical diagnosis, autosomal dominant inheritance should be presumed. Incomplete expression or even non-penetrance may occur, the latter perhaps due to gonadal mosaicism, which should be considered in the genetic counseling.

**FIGURE 148-11** Boys with AEC syndrome showing the scarring alopecia.

Direct molecular diagnosis is available to detect p63 mutations. Prenatal diagnosis could be done by molecular diagnosis. It has also been accomplished by ultrasonographic detection of the involved structures. However, the wide degree of clinical variability should be stressed.

## 148.6 ANKYLOBLEPHARON, ECTODERMAL DEFECTS, CLEFT LIP/PALATE (MIM 106260)

### 148.6.1 Clinical Features

Ankyloblepharon, ectodermal defects, and cleft lip/palate (AEC) syndrome, also known as Hay–Wells syndrome, is another disorder caused by p63 mutations. Affected individuals may have coarse, wiry, sparse hair, or may have scarring of the scalp with almost total alopecia (Figure 148-11). Almost all newborns have superficial skin erosions that can be patchy, or can involve large areas of the body. The erosions are most often on the scalp. Nails are absent or dystrophic. Sweating is subjectively decreased in this condition, but does not cause hyperthermia as in HED. The teeth may be conical in shape and reduced in number, and maxillary hypoplasia may be present. It has been reported that adults with AEC have an average of 4.75 permanent teeth (57). Cleft lip and/or palate are frequently associated, and alveolar synechiae (congenital adhesions between the upper and lower jaws) are occasionally seen. Fusion of the eyelids (ankyloblepharon filiforme adnatum) is a distinctive feature of the disorder seen in about 70% of cases and is a clue to the diagnosis in affected newborns. Lacrimal puncta may be absent with associated chronic blepharitis (58). The eyelashes may also be absent.

### 148.6.2 Genetics, Diagnosis, and Differential Diagnosis

AEC syndrome is an autosomal dominant disorder, allelic to the EEC3 locus, and caused by mutations in

the p63 gene (59–61). About 80% of the p63 mutations in AEC syndrome result in amino acid substitutions in the sterile alpha motif (SAM) domain and about 20% are in the transactivation inhibitory domain (TID) of the protein. The mutations are predicted to affect protein–protein interactions. Rapp–Hodgkin syndrome (RHS) is an allelic disorder with the AEC syndrome; these two disorders are very similar clinically and are primarily differentiated by the presence of ankyloblepharon in AEC syndrome (60,62). Some authors have suggested that AEC and RHS should be considered as the same syndrome, and that RHS is part of the spectrum of AEC syndrome. Clinical molecular testing of the p63 gene for AEC syndrome is available. It is generally suggested that sequencing of exons 13 and 14 should be done first, since these exons encode the SAM and TID domains where the vast majority of mutations are found. Sequencing of the rest of the p63 gene could be done if no mutation is found in exons 13 and 14, since rare AEC/RHS-like cases have had mutations outside these exons, and because there is quite a bit of clinical overlap among the other syndromes caused by p63 mutations. Deletion and duplication testing could also be done, although thus far, this has not been reported in AEC or RHS. Somatic and/or germline mosaicism has been suggested in a few families with multiple affected children and normal parents.

### 148.6.3 Management and Counseling

Dermatological evaluation and ongoing management of the skin erosions and other skin problems is required. Early attention should be given to the potential occurrence of serious scalp infections and sepsis in affected infants and children. Referral to plastic surgery for surgical correction of the cleft lip and/or cleft palate is needed, with follow-up treatment for any associated speech or hearing problems. Surgical treatment of the ankyloblepharon may be necessary, although some of these lyse spontaneously. Many individuals need ophthalmological care for lacrimal duct obstruction, dry eyes and blepharitis. Dental anomalies and hypodontia should be treated with appropriate prosthodontic care. Some infants and young children have growth and nutritional problems, and the involvement of a gastroenterologist and dietitian may be needed (63).

Genetic counseling should be provided regarding the autosomal dominant inheritance of the disorder. About 30% of affected infants have an affected parent and 70% represent new mutations. Somatic and germline mosaicism has been suspected in several families, and this should be discussed with regard to recurrence risks for future pregnancies. Prenatal molecular genetic diagnosis for the disorder is possible if a p63 mutation has been identified in the family.

## 148.7 RAPP–HODGKIN SYNDROME (MIM 129400)

### 148.7.1 Clinical Features

Rapp–Hodgkin syndrome (anhidrotic ectodermal dysplasia with cleft lip/palate) is another ectodermal dysplasia syndrome with orofacial clefting, which is also inherited as an autosomal dominant trait. However, ectrodactyly is not seen in this disorder. The Rapp–Hodgkin syndrome was originally described in a family with anhidrotic ectodermal dysplasia, cleft lip and palate, a narrow nose, and a small mouth. Trichodysplasia is present, with the scalp hair in childhood coarse and wiry, with microscopic descriptions of the hair reporting both pili torti (twisted hair) and pili canaliculi (canal-like depressions running the length of the shaft) (Figure 148-12). Alopecia of the scalp occurs in adulthood in affected females and males, as well as sparseness of the lateral eyebrows and eyelashes. Hypodontia, conical shaped teeth, and dysplastic nails occur. Although the numbers of sweat glands are reported to be reduced, clinical hyperthermia is usually not a problem. Submucous cleft or cleft of the uvula may be present, rather than frank clefting, along with maxillary hypoplasia. Occasional findings have included agenesis/atresia of the lacrimal puncta, hypospadias, atretic ear canals, and malformed auricles.

### 148.7.2 Genetics

Rapp–Hodgkin syndrome is inherited as an autosomal dominant trait with variable expression. This condition has significant clinical overlap with both the EEC and AEC syndromes, and they are all allelic disorders associated with mutations of the p63 gene. Mutations occur mainly in the SAM domain or the TID domain of the p63 protein (60,62,64–66). As mentioned above, RHS is considered by some authors to be part of the spectrum

**FIGURE 148-12** Girl with AEC/RHS syndrome showing the abnormal hair.

of AEC syndrome, and not a separate entity. Please refer to the molecular genetic testing strategy outline for AEC syndrome above.

### 148.7.3 Management and Counseling

The treatment for this disorder is essentially the same as for AEC. Management involves surgical correction of the cleft lip and palate and treatment of any speech or hearing problems. Surgical correction for atresia of the lacrimal puncta may be required. Hypodontia requires appropriate prosthodontic care, including dental implants in severe cases. Severe alopecia and balding can be treated with a wig. Families should be counseled that the disorder is inherited as an autosomal dominant trait with variable expression. At-risk individuals should be examined for any minimal involvement with the disorder. Molecular genetic diagnosis is possible by sequencing of the p63 gene, beginning with exons 13 and 14, and prenatal diagnosis could be performed if the mutation in the family is known.

## 148.8 ADULT (ACRO-DERMATO-UNGUAL-LACRIMAL-TOOTH) SYNDROME (MIM 103285)

ADULT syndrome resembles EEC syndrome but also displays excessive skin freckling (67). As with other syndromes allelic to EEC, mutations in the p63 gene have been described in ADULT syndrome, one in the DNA binding domain (DBD) of the gene that results in a possible unique gain-of-function (68,69) and others in the TA2 domain and just before the DBD (70).

## 148.9 LIMB-MAMMARY SYNDROME (MIM 603543)

Limb mammary syndrome (LMS) was originally described with major features of severe hand and foot anomalies with hypoplasia/aplasia of the mammary glands (56,71). However, minor features affecting the ectodermal appendages were also noted. Mutations of the p63 gene were subsequently described in families with LMS within the p63 SAM domain (53).

## 148.10 SPLIT HAND/SPLIT FOOT MALFORMATION (SHFM4) (MIM 605289)

Isolated ectrodactyly (split hand/split foot malformation) can be inherited as an autosomal dominant trait without other malformations. Five separate genetic loci have been identified in isolated split hand/split foot malformation. p63 plays an important role in the regulation of the formation and differentiation of the apical ectodermal ridge (AER), which is critical for limb development. p63

mutations were found in 4 of 35 families with SHFM in one study (53).

### 148.10.1 Differential Diagnosis

Roselli–Gulienetti (MIM 225000) syndrome is an ectodermal dysplasia syndrome with associated clefting but can be distinguished by the associated features. Odontotrichomelic (cleft lip/palate, tetrapromelia, and deformed pinnae), Bowen–Armstrong, and LADD syndromes all have some phenotypic overlap with EEC syndrome and the other p63-related disorders. The EEM (ectodermal dysplasia, ectrodactyly, and macular dystrophy) syndrome is inherited as an autosomal recessive trait and has been shown to be due to mutations at a separate genetic locus (CDH3) (72). Curly hair–ankyloblepharon–nail dysplasia syndrome (CHANDS) has some overlapping features, but does not have the skin changes or clefting seen in p63-related disorders. Ankyloblepharon filiforme adnatum can be inherited as a separate autosomal dominant trait. Some infants with AEC syndrome are misdiagnosed as having epidermolysis bullosa because of the skin erosions, and an incorrect diagnosis of ichthyosis might be made initially if a newborn with AEC has erythroderma or a collodion membrane.

## 148.11 HIDROTIC ECTODERMAL DYSPLASIA (CLOUSTON SYNDROME) (MIM 129500)

### 148.11.1 Clinical Features

Hidrotic ectodermal dysplasia, also known as Clouston syndrome, is an autosomal dominant disorder that affects the hair, nails, and skin. This condition was first reported in a large kindred that was originally from France and emigrated to Canada, the northeastern United States, and Scotland. However, Clouston syndrome has been reported in diverse ethnic and racial groups as well. There is complete penetrance with variable expressivity.

Individuals with Clouston syndrome have normal sweat and sebaceous gland function and normal teeth. The hair is abnormal and is fine, brittle, and slow-growing (Figure 148-13). Females may have total alopecia, while males may have patchy alopecia, typically with more hair present than affected females. The eyebrows and eyelashes are sparse. Axillary and pubic hair may be absent or sparse. The hairs have reduced tensile strength and a disorganized fibrillar structure with decreased cysteine and disulfide bonds and reduced birefringence in polarized light. Another characteristic feature is palmo-plantar hyperkeratosis. The palms and soles are thick and dyskeratotic. The nails are typically severely dystrophic. Nails can be discolored, thickened, and dystrophic,

**FIGURE 148-13** (A–D) Clouston syndrome.

or hypoplastic with a cone-shaped or triangular nail. The distal ends of the fingers are thickened and may appear clubbed. The skin of the knuckles, elbows, axillae, areolae and pubic area may be hyperpigmented. Breast development in females is normal. Ophthalmological defects include cataracts, photophobia, strabismus, conjunctivitis or blepharitis.

### 148.11.2 Genetics, Diagnosis and Differential Diagnosis

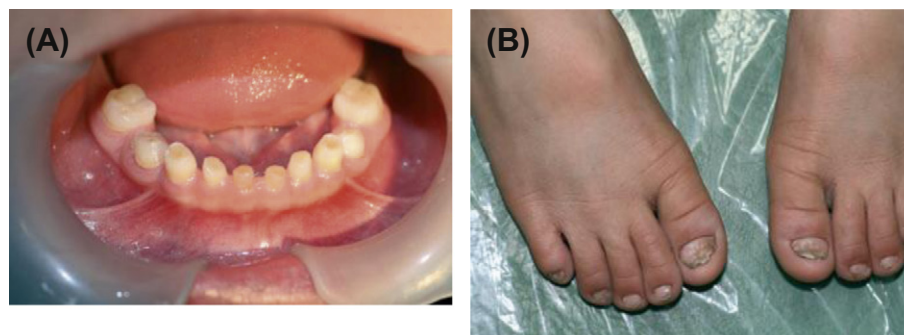

Clouston syndrome is caused by mutations in the gap junction protein beta-6 gene (GJB6). In 1996, Kibar mapped the locus for this disorder to the pericentromeric region of chromosome 13q, using linkage analysis in eight French-Canadian families. Lamartine et al. (2000) demonstrated mutations in the gene encoding connexin-30. One mutation, Gly11Arg, was found in individuals from several areas of Europe. More than 20 different connexin proteins have been identified. These proteins form connexons and allow communication between adjacent cells at gap junctions (73). Connexons are intercellular channels that regulate the exchange of ions, small metabolites, and secondary messengers between the cytoplasm of adjacent cells. Cell culture transfection studies of GJB6 mutations in Clouston patients demonstrated impaired trafficking of the protein to the plasma membrane, preventing the formation of functional Cx30 gap junctions. Mutations in different connexins are associated with hearing loss, and other dermatological and neurological disorders (74). Another missense mutation in the GJB6 gene causes autosomal dominant nonsyndromic

sensorineural deafness (DFNA3; MIM 601544). Mutations in GJB2 (connexin 26) cause non-syndromic deafness, palmoplantar hyperkeratoderma and the autosomal dominant syndrome Keratitis–Ichthyosis–Deafness (KID) (see further discussion below). Deafness is an uncommon feature in Clouston syndrome, although it has been reported.

The diagnosis of Clouston syndrome is based on the clinical findings and observation of an autosomal dominant pattern of inheritance. Molecular genetic testing of the GJB6 gene is clinically available. Targeted mutation analysis for the four common mutations, Gly11Arg, Ala-88Val, Val137Glu and Asp50Asn, should be performed first, followed by full sequencing if one of these mutations is not found (75–77). All individuals with typical features of Clouston syndrome have been found to have mutations in GJB6.

The condition may be distinguished from a number of other types of ectodermal dysplasias by its major involvement of the hair and nails, but with both normal teeth and sweat gland function. It should be distinguished from other conditions with alopecia and nail dysplasia, including onychodystrophy and alopecia inherited as simple autosomal dominant traits. Similar skin involvement of the palms and soles can be seen keratosis palmoplantaris with periodontopathia (MIM 245000). Pachyonychia congenita types 1 and 2 have focal palmoplantar hyperkeratosis and hypertrophic nail dystrophy, but the hair is not affected. Autosomal dominant and recessive hypohidrotic ectodermal dysplasia may have overlapping hair characteristics, but are associated with hypodontia and hypohidrosis, not seen in Clouston syndrome.

**FIGURE 148-14** A and B. Witkop syndrome with abnormal nails and teeth. (With permission Memarpour, M.; Shafiei, F. *Witkop Tooth and Nail Syndrome: A Report of Three Cases in a Family*. *Pediatric Dermatology* **2011**, 28 (3), 281–285.)

### 148.11.3 Management and Counseling

Dermatological treatment for the skin and nail involvement is recommended. Emollients can be used to treat the palmoplantar hyperkeratosis, which tends to worsen with age. The use of artificial nails may improve the appearance of the hands and feet. Total alopecia can be treated with wigs or hair pieces as appropriate. Families should be counseled that the condition is inherited as an autosomal dominant trait with variable expression. At-risk individuals should be examined closely for signs of the disorder because of the variable expression. Molecular diagnosis of mildly affected family members may be helpful if the GJB6 mutation is known. Pre-implantation and prenatal diagnosis are potentially available, again if the GJB6 mutation has been previously identified in the family.

## 148.12 TOOTH AND NAIL SYNDROME (WITKOP SYNDROME) (MIM 189500)

### 148.12.1 Clinical Features

Witkop syndrome is an autosomal dominant ectodermal dysplasia syndrome, first described by Dr. Carl Witkop in 1965. It is also called tooth and nail syndrome, since affected individuals have hypodontia and nail dysplasia (Figure 148-14). The incidence is about 1–2 per 10,000. The hair is usually normal, but is sometimes thin or fine. Heat tolerance and sweat gland function are normal. The nails are described as being small, spoon-shaped and slow-growing, and may fracture easily. Longitudinal ridges or pits in the nails may be seen. The nail dysplasia is usually more severe in childhood and may improve with age, such that there may be no obvious nail abnormalities in affected adults (78). Also, the toenails often have more significant abnormalities than the fingernails. Dental abnormalities include congenital absence of primary and/or permanent teeth. Sometimes, the abnormalities of the primary dentition are very subtle, and the condition is not recognized until the permanent teeth fail to erupt normally. The most common missing teeth are the mandibular incisors, maxillary canines and second molars. The teeth may be malaligned, conical in shape, or widely spaced. The teeth are described as being

parallel-sided with narrow crowns, or tapering toward the incisal edge. It is unusual for affected individuals to have more than 20 missing teeth, but this has been seen occasionally; more often, there are only a few missing teeth.

### 148.12.2 Genetics, Diagnosis, and Differential Diagnosis

Witkop syndrome is autosomal dominant with variable expression, caused by heterozygous mutations in the *MSX1* gene, which is the homolog of the *Drosophila* muscle segment homeobox 1 gene and is located at 4p16.1. In 2001, Jumlongras et al. studied a three generation family with Witkop syndrome using linkage analysis and a candidate gene approach and they identified a S202X nonsense mutation in the *MSX1* gene that cosegregated with the phenotype (79). They predicted that the mutation caused the phenotype via haplo-insufficiency. They then generated *Msx1*-knockout mice and demonstrated that both tooth and nail development were disrupted in the *Msx1*-deficient mice. *MSX1* mutations have also been found in patients with isolated tooth agenesis (80), with tooth agenesis and oral clefting (80), and with non-syndromic cleft lip and palate (81,82). *MSX1* interacts with other regulatory proteins, including *DLX* (distalless homeobox protein), *MSX2* (muscle segment homeobox 2 protein) and *TBP* (TATA-binding protein), and Jumlongras et al. (2001) postulated that the clinical variability of Witkop syndrome and other patterns of malformation associated with *MSX1* mutations may be related to the effects of these or other modifier genes.

With regard to the differential diagnosis, Witkop syndrome can be distinguished from hypohidrotic ectodermal dysplasia by its pattern of inheritance and by the lack of involvement of sweat glands. Hidrotic ectodermal dysplasia, or Clouston syndrome, has nail involvement but lacks dental involvement, and therefore, should be easily distinguished from Witkop syndrome. There may be an autosomal recessive form of tooth and nail syndrome; Fried reported first cousins from a consanguineous family with absent and conical-shaped teeth, thin concave toenails, and fine, slow-growing scalp hair (83). Simple oligodontia without nail involvement can be

inherited as a distinct autosomal dominant trait. PAX9, another transcription factor, is mutated in familial oligodontia with primarily molar involvement (84,85).

### 148.12.3 Management and Counseling

The main treatment for Witkop syndrome involves developing an appropriate dental treatment plan for the hypodontia (86). Families should be counseled regarding the autosomal dominant inheritance pattern with variable expression. At-risk family members should be examined carefully for any evidence of mild involvement with the disorder. Mutation analysis of the MSX1 gene can be performed in several clinical laboratories.

## 148.13 IKBKG GENE-RELATED DISORDERS

### 148.13.1 Incontinentia Pigmenti, Familial Male-Lethal Type (IP2) (MIM 308310)

**148.13.1.1 Clinical Features.** Incontinentia pigmenti (IP) is a complex X-linked disorder that can affect multiple ectodermally derived structures, including the central nervous system (CNS) and the eyes. The clinical features of IP have been reviewed in detail (87). The vast majority of affected individuals are female, although rare affected males have been reported (88). Ectodermal involvement is primarily of the teeth, hair, and skin, with minor involvement of the nails. Normal sweat gland function is present. Dental anomalies are seen in 80% of cases and may include hypodontia conical-shaped teeth, and delayed dental eruption, affecting both the deciduous and permanent dentition. Onychodystrophy is seen in 40% of individuals, usually consisting of mild ridging and pitting, but severe nail dysplasia occasionally occurs. Skin involvement occurs early during the first weeks of life and evolves over time through four stages (Figure 148-15). Stage I is seen at birth or in the first weeks of life, with erythema and

blistering of the skin, accompanied by eosinophilia. Stage II is the verrucous stage, manifested by warty or hyperkeratotic lesions that form in the area of the healing blisters. The verrucous lesions usually resolve with time. Stage III is associated with hyperpigmentation, with swirling gray or brown pigmentation frequently following the lines of Blaschko. The pigmentation usually fades with time and is undetectable in individuals over 20 years of age. Stage IV is the atretic stage, during which hypopigmentation and streaky alopecia are seen on the trunk and extremities. Patches of alopecia can also occur on the scalp, as well as thin sparse hair in some children. Breast and nipple hypoplasia are sometimes seen. Eye involvement is characterized by retinal vessel proliferation, similar to retinopathy of prematurity, which may proceed to retinal scarring and detachment (89). Other eye problems include cataracts, myopia, strabismus, microphthalmia and optic atrophy (90,91). Approximately 15–25% of affected individuals have been reported to have CNS problems such as developmental delays, seizures, spastic paresis and MRI abnormalities (87,90–92).

**148.13.1.2 Genetics, Diagnosis, and Differential Diagnosis.** Incontinentia pigmenti is an X-linked dominant trait, typically with prenatal lethality in males. This is supported by a high female-to-male ratio in affected families and an increased incidence of miscarriages. Rare affected males with an otherwise “lethal” mutation can be explained by somatic mosaicism or associated Klinefelter syndrome (47,XXY). The disorder was mapped to Xq28 and was subsequently shown to be due to mutations in the NF- $\kappa$ B essential modulator gene (NEMO), also known as the I- $\kappa$ B kinase-gamma (IKBKG) gene (93). Eighty percent of new mutations involve an 11.7kb deletion of exons 4–10, but point mutations and smaller deletions and duplications can occur (24,34,92). Mutations in IKBKG disrupt the NF- $\kappa$ B signaling pathway and may affect both developmental pathways and susceptibility to cellular apoptosis (34). IP cells with the common IKBKG 11.7kb deletion lack NF- $\kappa$ B activation, which normally protects against apoptosis; therefore, IP cells are susceptible to proapoptotic signals, and they die easily, which offers an explanation for the embryonic male lethality. In affected females, early death of the cells with an active X bearing the IP mutation and their replacement by cells with an active normal X leads to a skewed X-inactivation pattern.

The diagnosis of IP in infancy is usually straightforward if a typical rash is present, and skin biopsy can demonstrate the associated eosinophilia. The condition should be distinguished from other neonatal skin disorders such as epidermolysis bullosa and bullous impetigo. Diagnosis in older children and adults is more difficult and should be distinguished from hypomelanosis of Ito, which can have both pigmentary abnormalities (depigmentation) and CNS involvement. Hypomelanosis of Ito has been associated with chromosomal mosaicism.

**FIGURE 148-15** Typical skin lesions in incontinentia pigmenti.

**148.13.1.3 Management and Counseling.** Referral to a dermatologist in the neonatal period is recommended for appropriate care of the blistering skin lesions and to manage any skin infections or cellulitis. Serial ophthalmological examinations are needed during infancy to monitor for neovascular changes and to identify other associated eye anomalies. Ocular screening exams have been suggested at birth, monthly until three to four months, every three months until one year of age, and then biannually until three years of age (94). There have been reports of successful treatment of the retinopathy by both cryotherapy and laser photocoagulation (89). Referral to a neurologist should be made if necessary for seizures, spasticity or focal deficits and an MRI scan of the brain should be performed if there are retinal changes or neurological abnormalities (95,96). Appropriate dental care should be provided for hypodontia or conical-shaped teeth.

Affected females should be counseled that one half of their daughters will be carriers and that one half of their male offspring will result in a spontaneous abortion. Since most skin changes may have resolved or could be very minimal, determining the carrier status of adult females by clinical examination can be difficult. Careful dental and retinal examination should therefore be performed. Molecular testing of the IKBKG gene is available for clinical diagnosis, as well as for carrier testing and prenatal diagnosis. Approximately 65% of affected females have the 11.7kb deletion of exons 4–10. Other intragenic deletions and duplications as well as substitutions have been reported, and IKBKG gene sequencing can be performed if the common deletion is not found. X-inactivation studies on leukocytes to look for skewing can be done on females in whom no mutation can be found, but this is not specific for IP.

## 148.13.2 Hypohidrotic Ectodermal Dysplasia with Immune Deficiency (HED-ID) (MIM 300291)

Hypomorphic mutations in the IKBKG gene cause a related X-linked disorder, hypohidrotic (anhidrotic) ectodermal dysplasia with immunodeficiency. There is also a rare disorder, hypohidrotic ectodermal dysplasia with immunodeficiency, osteopetrosis, and lymphedema (OL-HED-ID) caused by a IKBKG mutation (MIM 300301) (33,97).

**148.13.2.1 Clinical Features.** Male individuals with clinical features typical of XLHED were identified who had severe recurrent infections, including miliary tuberculosis, *Pseudomonas aeruginosa*, *Staphylococcus aureus* and *Streptococcus pneumoniae*. Subsequently, they were found to have hypomorphic mutations in the NKBKG (NEMO) gene. Affected males have severe hypogammaglobulinemia and impaired antibody response to polysaccharides. Impaired natural killer (NK)-cell activity is seen in some cases. The abnormalities of hair, teeth, and eccrine sweat glands can be either identical to or milder than findings in individuals with XLHED or ARHED

(Figure 148-16). A few patients have been reported with osteopetrosis and lymphedema in addition to the other features; they were found to have a mutation in the stop codon (X420W) that adds 27 extra amino acids to the IKBKG protein and decreases its stability (98).

**148.13.2.2 Diagnosis.** Diagnosis is suggested by the clinical phenotype in combination with a history of recurrent infections. Mutation analysis of the NKBKG gene is clinically available to confirm the diagnosis.

**148.13.2.3 Management and Counseling.** Management of the HED-related medical problems is the same as for XLHED. Involvement of an immunologist and other

**FIGURE 148-16** (A and B) Boy with HED-ID syndrome due to hypomorphic IKBKG mutation. (With permission from Orstavik, K. H.; Kristiansen, M.; Knudsen, G. P.; Storhaug, K.; Vege, A.; Eiklid, K.; Abrahamsen, T. G.; Smahi, A.; Steen-Johnsen, J. Novel Splicing Mutation in the NEMO (IKK-gamma) Gene with Severe Immunodeficiency and Heterogeneity of X-chromosome Inactivation. *Am. J. Med. Genet.* 2006, 140 (1), 31–39.)

subspecialists as needed are required to manage the serious and recurrent infections.

### 148.13.3 Autosomal Dominant Hypohidrotic Ectodermal Dysplasia with Immune Deficiency (MIM 164008)

A boy with clinical features of HED-ID was reported in whom a heterozygous gain-of-function mutation was found in the *IKBA* gene (99). This gene encodes the  $\text{I}\kappa\text{B}\alpha$  protein in the EDA signal transduction pathway. The mutation enhanced the inhibitory capacity of  $\text{I}\kappa\text{B}\alpha$  and resulted in impaired NF- $\kappa\text{B}$  activation. The patient had a severe T-cell immunodeficiency in association with sparse scalp hair and conical teeth.

### 148.13.4 Tricho–Dento–Osseous Syndrome (MIM 190320)

**148.13.4.1 Clinical Features.** Tricho–dento–osseous (TDO) syndrome is a rare autosomal dominant disorder which involves the teeth, hair, and nails (100). Affected individuals also have increased bone density. The hair is kinky and curly, especially during the neonatal period. The nails may show thick cornification and splitting of the superficial layers. Dental findings include enamel hypoplasia and hypocalcification, with taurodontism (enlargement of the body of the tooth and the pulp chamber) of both the deciduous and permanent molars. Affected individuals with this disorder have both normal sweat gland function and normal skin. Skeletal findings include mild to moderate increase in bone density of the long bones and skull, with dolichocephaly of the cranium due to sagittal synostosis (101). There is considerable phenotypic variability in this disorder.

**148.13.4.2 Genetics, Diagnosis, and Differential Diagnosis.** TDO is inherited as an autosomal dominant trait. It was mapped in four kindreds from North Carolina to chromosome 17q21, and a 4-bp deletion in the human distal-less homeobox gene (*DLX3*) was found which correlated with the TDO phenotype in six families (102). The mutation is predicted to cause a frameshift and premature termination codon, resulting in a functionally altered *DLX3* protein. Other mutations in *DLX3* are associated with more severe phenotypes (103,104). The *DLX3* protein is a putative transcriptional activator implicated during development and differentiation of epithelial tissues (105). *DLX3* has been shown to regulate hair follicle differentiation and cycling (106). Transgenic mice expressing mutant *DLX3* were shown to have disruption of odontoblast polarization and defective dentin (107).

TDO syndrome has the same dental findings seen in another autosomal dominant disorder with only dental involvement, amelogenesis imperfecta (hypomaturational–hypoplasia type) with taurodontism (AIHHT) (MIM 104510). Sequencing of the *DLX3* gene in a family with AIHHT identified a two base pair deletion within the

homeodomain of *DLX3*. Thus at least some families with AIHHT are allelic with TDO and a phenotype–genotype difference may exist.

**148.13.4.3 Management and Counseling.** Management includes dental care for the enamel hypoplasia. Genetic counseling regarding the autosomal dominant inheritance pattern with variable expression should be provided. No clinical molecular testing is available yet for either confirmation of the diagnosis or prenatal diagnosis.

### 148.13.5 Goltz Syndrome (Focal Dermal Hypoplasia) (MIM 305600)

**148.13.5.1 Clinical Features.** Goltz syndrome, also known as focal dermal hypoplasia, is a rare X-linked dominant disorder associated with defects in tissues of both ectodermal and mesodermal origin (108). The characteristic feature is patchy dermal hypoplasia with herniation of fat through the dermal defects. The phenotype is highly variable, but many patients with Goltz syndrome have significant craniofacial dysmorphic features and complex ocular anomalies in addition to ectodermal abnormalities (Figures 148-17 and 148-18). They may have mild microcephaly and facial asymmetry with a pointed chin. The ears may be lowset, protruding or with a simplified helical shape, and the auditory canals may be narrow. Mixed sensorineural and conductive hearing may be present. There are frequent ophthalmological complications, including microphthalmia (15%), anophthalmia, aniridia (3%), or ectopia lentis (6%). Strabismus or nystagmus can occur. There may be iris and/or choroidoretinal colobomas, or optic atrophy. The nasal bridge may be narrow with a broad nasal tip or notched alae nasi. Cleft lip, with or without cleft palate, and papillomas of the gingiva or lips have been described. Papillomas of the larynx and esophagus have been reported as well. Arborescent papillomas of the axillae, periumbilical area, anus and vulva have also been seen. With regard to the teeth, hypodontia, enamel hypoplasia and delayed eruption are common. Notched incisors may be present. There may be supernumerary nipples, asymmetry of the breasts or athelia. A variety of diaphragmatic and abdominal wall defects may be associated with Goltz syndrome, including diaphragmatic hernia or hiatal hernia, diastasis recti, umbilical hernia, or even omphaloceles. Anteriorly displaced anus, intestinal malrotation, and renal anomalies such as horseshoe kidney or hydronephrosis have also been reported. Recently, Pentalogy of Cantrell has been identified in a patient with Goltz syndrome (109).

Skin findings include linear or reticular hyperpigmentation or skin atrophy with localized deposits of superficial fat. There may be hypoplastic fingertip epidermal ridges, absent fingernails and toenails, or dystrophic nails that are spoon shaped or grooved. Other digital anomalies include syndactyly, polydactyly or ectrodactyly. Hair abnormalities include sparse or brittle hair, often with patchy alopecia of the scalp. Intellectual disability is

found in about 15% of cases, and short stature in some. Brain defects can include hydrocephalus, agenesis of the corpus callosum or Arnold–Chiari malformation. The majority (90%) of cases are seen in females; about 95% are sporadic and 5% are inherited from a parent, usually the mother. Affected liveborn males (10% of cases) are all the result of a new somatic mosaic mutation; it is presumed that hemizygous non-mosaic males would be non-viable.

**148.13.5.2 Genetics and Diagnosis.** Goltz syndrome is due to mutations or deletions of the *PORCN* gene which is located at Xp11.23. In 2007, Grzeschik et al. studied

a group of patients with Goltz syndrome, including six individuals from one family and 10 additional unrelated individuals, using comparative genomic hybridization; they found deletions in two patients at Xp11.23 that shared four genes within an 80 kb overlapping region, including the *PORCN* gene (110). At the same time, Wang et al. amplified and sequenced all coding exons of the *PORCN* gene in 15 girls with confirmed or suspected Goltz syndrome, and they identified heterozygous mutations in 10 of the cases (111). In one of these cases, low level signal for the mutation was identified in the girl's father suggesting somatic mosaicism, but all other parental samples were negative for the mutation, consistent with new mutations in the affected girls. Analysis of additional cases by Grzeschik, Leoyklang and others has identified a variety of missense, nonsense and splice site mutations in the *PORCN* gene, confirming that this is the gene responsible for Goltz syndrome (110,112).

The *PORCN* gene encodes the human homolog of *Drosophila* porcupine. There are five isoforms of the gene product that are derived from alternative splicing, and are expressed in multiple tissues. In mice and *Drosophila*, the protein has been shown to be required for secretion of WNT proteins needed for activation of target genes in many developmental pathways. In mouse embryos, *Porcn* is expressed in most of the same tissues that are affected by anomalies in humans with Goltz syndrome.

**FIGURE 148-17** Goltz syndrome.

**FIGURE 148-18** Goltz syndrome features. (With permission from Maas, S. M., et al. Phenotype and Genotype in 17 Patients with Goltz–Gorlin Syndrome. *J. Med. Genet.* **2009**, 46 (10), 716–720.)

Clinical molecular testing is available for the PORCN gene. Mutations in affected individuals have included nonsense, frameshift, missense mutations, as well as deletions of the entire gene (113). Sequencing of the PORCN gene should be performed in females, followed by deletion testing by FISH or array CGH if no mutation is found. Males suspected of having Goltz syndrome should have sequencing of the gene; no affected male has been found to have a deletion. Mosaicism for PORCN mutations has been reported. Parents of affected girls should be examined for subtle signs of the disorder. Prenatal and pre-implantation diagnostic testing are both available if the disease-causing mutation is known in the family.

**148.13.5.3 Management and Counseling.** Because of the potential for multiple anomalies, a full evaluation should be completed including imaging of the brain, skeleton, and chest and abdominal organs, ophthalmology examination and audiological evaluation. Syndactyly and split-hand/foot malformation may require surgical correction or other intervention. Affected individuals should also be monitored for scoliosis. Follow-up with an otolaryngologist is often needed to evaluate for the papillomas in the oropharynx and airway, especially prior to endotracheal intubation for surgery. Dermatology consultation for long-term management of the skin lesions is required.

Genetic counseling regarding the X-linked dominant inheritance pattern should be given to the family. Since the majority of cases represent sporadic new mutations, the recurrence risk for most families will be low, but careful evaluation of the parents in combination with molecular diagnostic testing is necessary to provide the most accurate recurrence risk information.

### 148.13.6 KID (Keratitis–Ichthyosis–Deafness) Syndrome (MIM 242150)

**148.13.6.1 Clinical Features.** KID (Keratitis–Ichthyosis–Deafness) syndrome is a rare autosomal dominant condition associated with keratitis, ichthyosiform skin lesions and sensorineural hearing loss (114). There is generalized thickening of the skin, palmoplantar keratoderma, and erythematous verrucous skin lesions (Figure 148-19). The erythematous plaques are sharply demarcated and are seen on the face and limbs. The thickening of the skin appears in infancy. About half of affected individuals have recurrent skin infections, including bacterial and fungal infections. Alopecia is seen in at least 80% of cases, and can range from total scalp alopecia to minimal loss of eyebrows or eyelashes. Some individuals have sparse fine hair without alopecia. Nail dystrophy is also a very frequent feature. Sweating may be reduced. The teeth can be normal, but may have delayed eruption, brittleness or tendency for caries. Eye problems result from keratoconjunctivitis sicca with corneal vascularization and decreased vision. The hearing loss is congenital and non-progressive.

**148.13.6.2 Genetics.** KID syndrome is caused by mutations in the gene for connexin 26 (GJB2). 78–87% of cases have the Asp50Asn mutation, but other missense mutations have been described, possibly associated with a more severe phenotype. The Ser17Phe mutation was associated with development of squamous cell carcinoma of the tongue (114). About 65% of affected individuals represent new mutations, but familial cases occur as well. Germline mosaicism was suspected in a family with two affected children and normal parents (114).

**148.13.6.3 Management and Counseling.** Dermatology consultation with continued follow-up is required for the skin manifestations. Affected individuals should be monitored for squamous cell carcinoma of the skin or tongue, which has been seen in at least 10% of cases. Ophthalmology follow-up for progressive eye manifestations is required. Corneal transplant has been tried to treat the corneal vascularization. Audiology evaluation is needed for hearing aids and possible cochlear implants to treat the hearing loss.

Molecular diagnostic testing is available clinically. Genetic counseling regarding the autosomal dominant inheritance pattern should be provided.

### 148.13.7 Oculo–Dento–Digital Dysplasia (MIM 164200)

**148.13.7.1 Clinical Features.** Oculo–Dento–Digital dysplasia (ODDD) is an autosomal dominant disorder with variable expression. Affected individuals have sparse hair, enamel hypoplasia, camptodactyly and distinctive facial features with small eyes. The scalp hair is dry, sparse and slow-growing. Eyebrows and eyelashes may be absent or sparse. Both the deciduous and permanent teeth have enamel hypoplasia and are prone to decay. They are small, yellowish and friable. Sweat glands, skin and nails are normal. The eyes have short palpebral fissures, with microcornea and or micropthalmia, although the vision is usually normal. There is a narrow nose with hypoplastic ala nasi. Bony abnormalities include camptodactyly of the fourth and fifth fingers in over 80% of case, hyperostoses of the skull, broad ribs and clavicles, and abnormal trabeculation of the long bones. Syndactyly of the fourth and fifth fingers and toes may be present.

**148.13.7.2 Genetics.** ODDD is caused by mutations in the connexin-43 gene (GJA1) localized to chromosome 6q22–q23 (115–117).

**148.13.7.3 Management and Counseling.** Dental care for the enamel hypoplasia is necessary. Vision is usually normal, but 10–15% of affected individuals develop glaucoma, so they should be followed by an ophthalmologist periodically.

Genetic counseling regarding autosomal dominant inheritance with variable expression should be provided. Clinical molecular genetic testing is available for the GJA1 gene.

**FIGURE 148-19** (A–D) KID syndrome features. (With permission from Mazereeuw-Hautier, J., et al. *Keratitis–Ichthyosis–Deafness Syndrome: Disease Expression and Spectrum of Connexin 26 (GJB2) Mutations in 14 Patients*. *Br. J. Dermatol.* **2007**, 156 (5), 1015–1019.)

### 148.13.8 Ectodermal Dysplasia–Ectrodactyly–Macular Degeneration (EEM) Syndrome (MIM 225280)

**148.13.8.1 Clinical Features.** Ectodermal dysplasia–ectrodactyly–macular degeneration (EEM) syndrome is a rare autosomal recessive disorder. It is characterized by sparse scalp hair, eyelashes and eyebrows, small, widely spaced teeth, agenesis of some teeth, limb anomalies including ectrodactyly, syndactyly and camptodactyly and macular dystrophy. Affected individuals have normal sweating. The visual acuity gradually decreases with progression of the retinal degenerative abnormalities. The presence of macular dystrophy distinguishes it from other ectodermal dysplasia syndromes with limb malformations.

**148.13.8.2 Genetics.** Mutations in the CDH3 gene for cadherin-3 have been identified in several families with EEM (72,118). CDH3 is expressed in the apical ectodermal ridge and the interdigital mesenchyme in mice, which is compatible with the limb abnormalities seen in EEM. A related disorder, congenital hypotrichosis with juvenile macular dystrophy (HJMD), is also caused by CDH3 mutations, but the mutations are distinct in the two syndromes. Clinical molecular genetic testing is available in Europe for the CDH3 gene.

**148.13.8.3 Management and Counseling.** Management of the dental, limb and hair concerns are the same as for the other ED disorders discussed above. Long-term ophthalmological care will be needed for the visual concerns. Genetic counseling with regard to the autosomal recessive inheritance of the disorder should be provided.

This article is a revision of the previous edition article by Julia A Newton Bishop, volume 3, pp 3563–3578, © 2007, Elsevier Ltd.

### 149.1 INTRODUCTION

The three structural components of the skin are the epidermis, the dermis and the skin appendages. The epidermis is the most cellular layer and the main cell population is composed of keratinocytes dedicated to terminal differentiation and the production of stratum corneum. Within the epidermis there are also melanocytes, a dendritic cell population usually found in the basal layer of the epidermis in a ratio of around one melanocyte to every 10 basal keratinocytes. In the mid-epidermis there is a significant population of the second dendritic cell component of the epidermis, the antigen presenting Langerhans cell. The Merkel cell is seen in and around the basal layer of the epidermis. Keratinocytes give rise to squamous cell carcinoma, and precursor lesions (such as actinic keratoses, and Bowen's disease). Although basal cell carcinomas arise in the epidermis, the cell of origin remains controversial (1). Melanocytes give rise to melanoma and benign melanocytic nevi. Langerhans cells give rise to Langerhans cell histiocytosis and Merkel cells to Merkel cell carcinoma.

The dermis contains fibroblasts and mast cells, and other structures such as the vasculature, smooth muscle and neural tissue all have their own cell population, each with the potential for malignant change.

The third major components are the skin appendage structures. These include the hair follicle and the sebaceous gland, frequently referred to as the pilosebaceous unit. The apocrine gland and erector pili muscles may also be found in association with this structure. The eccrine sweat glands provide a separate discrete appendageal cell population.

All the cell types present in the epidermis, dermis, and skin appendages have the capacity for malignant change (2), and skin cancer is common and becoming increasingly so. Sixteen to forty four percentage of Americans were predicted to develop skin cancer in their lifetime at the beginning of this century (3). By far the most common cutaneous malignancy is the basal cell carcinoma, while the type responsible for the majority of deaths is that arising from the melanocyte, melanoma.

Tumors arising from the dermis are much less frequent, but may arise from, for example, the vasculature (such as angiosarcomas and Kaposi sarcoma). A wide variety of tumors arise from the skin appendages, but all are rare, and are usually locally expansive without metastatic potential. They are of interest to geneticists, however, in that a number of rare genetic conditions are associated with specific skin appendage tumors, such as sebaceous gland tumors in the Muir–Torre syndrome.

As for most cancers, rare individuals and families exist in which there is a markedly increased risk of skin cancer due to inherited so-called highly penetrant cancer genes. These families are said to have a family cancer syndrome, and such syndromes are typified by family members having cancers earlier in life than average, and having multiple primary cancers as well as having more than expected numbers of cancers in the family. Most increased susceptibility however results as a result of a combination of inherited, less penetrant genes (which each increase the risk only a little but the individual may have inherited several different low penetrance genes) and causal environmental exposures.

In this chapter we will predominantly discuss the three most common types of skin cancer, basal cell carcinoma, squamous cell carcinoma and melanoma. We will describe something of their clinical features, then we will explore first what is known of the common lower penetrance susceptibility genes and second the family cancer syndromes associated with each type of skin cancer.

### 149.2 BASAL CELL CARCINOMA

Basal cell carcinomas (BCC) arise from the epidermis and the BCC is the commonest form of cutaneous malignancy, found mainly on the face. The cell of origin surprisingly remains controversial. The observation discussed below that these cancers occur in individuals with the Bazex–Dupre–Christol syndrome in which the hair follicle is clearly abnormal might suggest that the cell of origin may be follicular, as has recently been argued by Seykora et al. on the basis of cell biology (1). Very rarely however these

tumors have been reported on the palm (which is clearly not hair bearing) which has given rise to the suggestion that the cell of origin was a progenitor of an eccrine cell (sweat gland) or an epidermal stem cell (4). Variation in the incidence of basal cell carcinoma geographically suggests that the main etiological factor is sun exposure (in that it is most common where fair skinned people live in hot countries such as Australia), although the evidence for a clear linear relationship between the incidence of basal cell carcinomas and cumulative lifetime sun exposure is not as obvious as it is for squamous cell carcinoma. Indeed there is a view that basal cell carcinomas share with melanoma an association with intermittent (holiday) rather than cumulative sun exposure, and there is a corresponding higher risk in individuals of higher socioeconomic status who have more access to holiday sunshine (5). Basal cell carcinomas are becoming more common over time. A study from New Hampshire reported an incidence per 100,000/year of 310 for males and 166 for females for 1993–1994, with a 4% rise per year for both sexes over a 15-year period (6). In Europe there is similar evidence for marked increases in incidence as above, especially in females on the body, which was attributed to changed patterns of intermittent sun exposure (7,8).

### 149.2.1 Clinical Features and Pathology

Basal cell carcinomas (BCC) develop as slow-growing nodules mainly on the central part of the face, although they may occur on the trunk and on the limbs. The lesions appear initially as small round translucent papules, often with telangiectatic blood vessels on the raised rolled edge. The lesion expands slowly over months and years and may break down to develop an ulcerated center. Left untreated, these lesions will spread locally and destroy soft tissue cartilage and even bone, hence the alternative name *rodent ulcer* but metastases are fortunately very rare (Figure 149-1).

The pathology is that of tongues of epidermal cells invading the dermis but retaining a connection with the

overlying epidermis; the lateral border of these invading clusters of cells has a margin of palisaded cells. In addition, there is a surrounding stroma, which is an integral part of the tumor and which is particularly prominent in the morpoeic (scarring) variant.

### 149.2.2 Genetics of BCC

BCC are usually sporadic although there is genetic variation between individuals in terms of susceptibility. The strongest determinant of risk is skin color, as BCC are seen predominantly (but by no means exclusively) in white skinned peoples. Attempts are being made to identify common low to medium penetrance susceptibility genes using genome wide association studies (GWA) and candidate gene approaches. Given that BCC are most common in fair skinned people, GWA and candidate gene studies have identified genes which determine skin color (pigment genes) as BCC susceptibility genes. Red haired individuals are particularly sun-sensitive and therefore it is not surprising that variants in genes associated with red hair are associated with increased risk—such as the melanocortin 1 receptor gene (*MC1R*) (9–12) and the agouti signaling protein locus (*ASIP*) (13). The *MC1R* variants result in increased proportions of red/yellow pigment in the skin and hair and this is associated with increased risk of sunburn. Polymorphisms in other pigment genes are also associated with risk of BCC, such as the oculocutaneous albinism A2 gene *OCA2* (13) and the locus *SLC45A2* (14) and most recently the interferon regulator gene 4, *IRF4* (15). A recent meta-analysis suggested that both pigment genes and other genes not associated with pigmentation are associated with risk (16). Loci not known as yet to be associated with pigmentation but which have been shown to be associated with susceptibility in GWA include a gene coding for keratin 5, a locus near to the *CDKN2A* locus at 9p and *TERT* which codes for telomerase and therefore impacts on telomere length (14,17). A GWA also identified a signal at chromosome 1p36 which contains a number of candidate genes (*PAD14*, *PAD16*, *RCC2* and *ARHGEF10L*), and another at 1q42 in the region of the ras-homolog *RHOA* (18). There are a number of relatively small candidate gene studies reported to have shown a relationship with risk of basal cell carcinoma, but these are difficult to evaluate given their size and lack of adequate validation and therefore will not be listed here.

There are two inherited syndromes in which there is a marked propensity to BCC: the nevoid basal cell carcinoma syndrome and the Bazex–Dupre–Christol syndrome, which are described here (Figure 149-2). Progress in understanding these syndromes has led to an increased understanding of the somatic genetic events in BCC. A third, called Rombo syndrome, is a very rare entity characterized by the presence of atrophoderma vermiculatum of the face, multiple milia, telangiectases, acral erythema and a propensity to develop basal cell carcinomas (19). The authors have not seen this condition

**FIGURE 149-1** A pigmented superficial basal cell carcinoma arising on the chest.

and do not know its relationship, if any to the Bazex–Dupre–Christol syndrome.

### 149.3 NEVOID BASAL CELL CARCINOMA SYNDROME (GORLIN–GOLTZ SYNDROME)

The nevoid basal cell carcinoma syndrome, transmitted as an autosomal dominant trait, was described by Howell and Caro (20) and by Gorlin and Goltz (21). The disease has nearly complete penetrance and variable expressivity (22). In the UK, around 1 in 30,827 people are affected (prevalence) (23). Gorlin estimated

that about 40% of cases represent new mutations [see OMIM (Online Mendelian Inheritance in Man)] and a more recent estimate was 26% (23). The median age of diagnosis for non-familial cases tends to be later (23 years, range 3–39 years) than for familial cases (12 years, range 0–44 years) (23). Farndon reported that 1 in 200 patients with BCC had Gorlins, falling to 1 in 5 with first diagnosis under the age of 19 years (24).

#### 149.3.1 Clinical Features

Affected individuals have a combination of congenital skeletal defects plus a tendency to develop tumors,

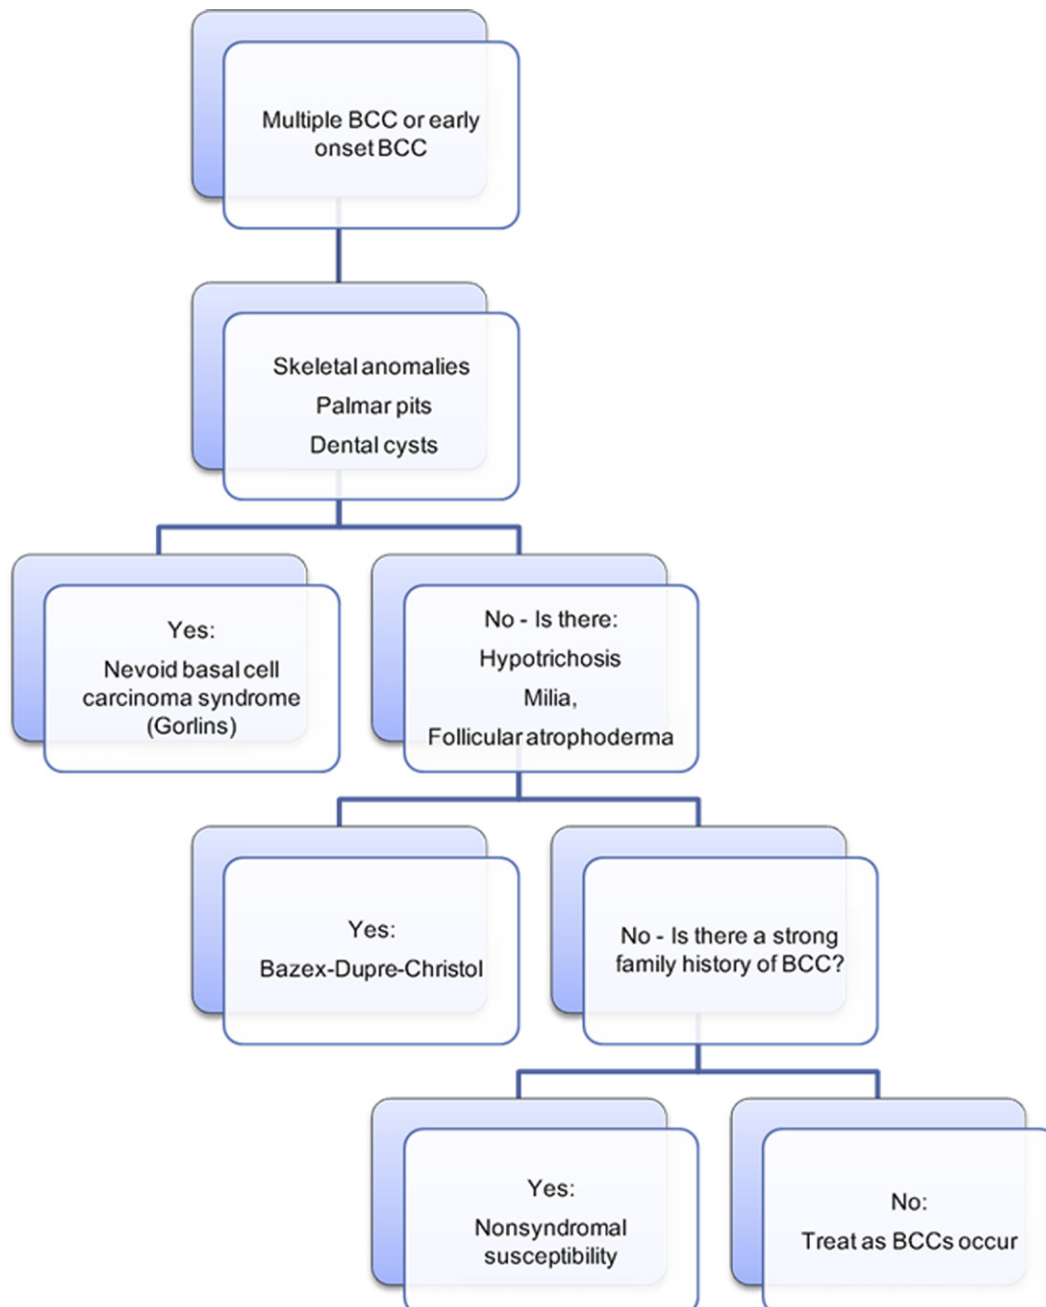

FIGURE 149-2 Investigation of early onset or multiple basal cell carcinomas.

including multiple basal cell carcinomas, ovarian fibromas (25), and medulloblastomas in affected children. Rarely, other tumors develop such as fibrosarcomas but the more common ovarian fibromas are of low malignant potential (26). Developmental anomalies include mild mandibular prognathism, lateral displacement of the inner canthi, frontal bossing, kyphoscoliosis, short metacarpals, abnormal ribs and calcification of the falx cerebri.

Hamartomatous cysts are well described in multiple sites such as the lungs and intestine. Affected patients have radiosensitivity so that multiple BCC have been seen in cutaneous radiation fields and multiple meningiomas have been reported in patients with this syndrome treated with radiotherapy for medulloblastoma (27). Radiotherapy is therefore to be avoided in affected patients where possible.

The most common first symptomatic presentation is to dental surgeons as a result of mal-aligned teeth due to jaw cysts (keratocysts), although the majority of cysts are small and are only picked up on X-ray. 75% of cases in the series reported by Kimonis had jaw cysts, 80% arising before the age of 20 years (28). The cysts are usually locally removed and examined pathologically, with more radical surgery used for locally recurrent tumors.

The skin signs are of small pits in the skin of the palms and soles, which often look pink especially after immersion in water, and when viewed with the dermatoscope. 90% of patients have pits (28) although the number of pits is very variable. Basal cell nevi start to arise around puberty and are initially tiny: 1–2 mm diameter lesions, often pigmented and most numerous in sun-exposed areas of skin. Only a small proportion of these lesions evolve into BCC, generally beginning in the second decade (Figure 149-3). The basal cell carcinomas are initially unusually small and may be missed if careful examination is not performed at regular supervision visits. Although the lesions in sporadic basal cell carcinoma are concentrated on the face, a high proportion of lesions in Gorlin syndrome are found on the trunk. Gene-environment (sun exposure) interaction is illustrated by the lower penetrance of skin cancers in black patients with the syndrome (29) and higher penetrance in families living at lower latitudes where sun exposure is more intense (30). Protection from the sun is therefore an important part of management, with a consequent need for vitamin D supplementation.

### 149.3.2 Molecular Genetics of Familial and Sporadic Basal Cell Carcinomas

Mutations in the *PTCH* gene at 9p 22.3 have been shown to be the cause of the nevoid basal cell carcinoma syndrome (31,32). Wicking reported 28 mutations in the *PTCH* exons in 71 probands, but genotype/phenotype correlations are poor and it seems likely

**FIGURE 149-3** A BCC arising on the eyelid of a patient with nevoid basal cell carcinoma syndrome.

that modifier genes exist (33,34). Patched is the protein product of *PTCH*, and is a key component of the Hedgehog signaling pathway driving cell proliferation. It is the cell membrane receptor for the Hedgehog family of proteins which are important in embryological development, drawing parallels with developmental anomalies in the nevoid basal cell carcinoma syndrome. *PTCH* has 23 exons encoding a transmembrane glycoprotein of 1447 amino acids. Most reported germline mutations have been frameshift or nonsense mutations leading to truncated Patched proteins. A French paper reported 29 mutations detected in 65 patients with the syndrome and, in common with other studies, the majority were frameshift resulting in loss of the last group of six transmembrane domains of the Patched protein (22). It is assumed that the syndrome is an example of Knudsen's two hit hypothesis wherein germline mutations of *PTCH* represent the first "hit" on the tumor suppressor gene, and that somatic changes in the second *PTCH* allele represent the second "hit," although in a recent report only 13/44 cases fit the two hit model (35).

Subsequently somatic mutations in *PTCH* and associated genes have been reported commonly in sporadic BCC, (36–38) and many of these mutations have a characteristic "UV signature" (39) so that investigation of the nevoid basal cell carcinoma syndrome has contributed much to understanding the carcinogenesis of BCC in general. Stone and colleagues (40) subsequently observed that human Patched forms a physical complex

with the vertebrate homologue of the drosophila protein, called Smoothed (SMO), and suggested that SMO was a signaling component linked to *PTCH* and in control of Sonic Hedgehog function. Their observations were confirmed by Xie et al. (41) who reported activating *SMO* mutations in sporadic basal cell carcinomas, showing that wild type *PTCH* and *SMO* genes both act as tumor suppressor genes for basal cell carcinoma, and that mutated *SMO* could function as an oncogene in basal cell carcinoma. The specific *PTCH* mutations for basal cell carcinomas and their absence in other skin tumors except for the very similar tricoepithelioma has been confirmed (42). Interestingly, an animal model for the nevoid basal cell carcinoma syndrome exists, in which one copy of *PTCH* is inactivated, hypersensitivity to ionizing radiation is demonstrable and chronological development of tumors from basaloid proliferations towards infiltrative tumors can be demonstrated and are presumed to result from sequential multi-step genetic events (43).

In drosophila, Hedgehog signaling requires the presence of the transcription factor cubitus interruptus, which shows homology to the Gli family of transcription factors in vertebrates (for a review, see Dicker et al. 2002 (39)). The induction of the transcription factor Gli 1 has been observed in basal cell carcinomas (44) and Gli 1 protein has been reported to be expressed in the cytoplasm of basal cell carcinomas (45). Thus there is a clear pathway of molecular genetic events implicating Sonic Hedgehog, *PTCH*, *SMO* and Gli 1 leading to development of familial and sporadic basal cell carcinomas.

### 149.3.3 Diagnosis of Nevoid Basal Cell Carcinoma Syndrome

A diagnosis can be made if two major or one major and two minor criteria are fulfilled.

#### Major Criteria.

- Multiple (>2) basal cell carcinomas (BCC) or BCC occurring under age 30 years or >10 basal cell nevi.
- Odontogenic keratocyst (histologically proven) or polyostotic bone cyst.
- Three or more palmar or plantar pits.
- Ectopic calcification: lamellar or early (<20 years) falx calcification.
- First degree relative with nevoid basal cell carcinoma syndrome.

#### Minor Criteria.

- Congenital skeletal anomaly: bifid, fused, splayed or missing rib or fused vertebrae.
- Occipitofrontal circumference >97th centile with bossing.
- Cardiac or ovarian fibroma.
- Medulloblastoma.
- Lymphomesenteric cysts.

- Congenital malformation: cleft lip and/or palate, polydactyly, eye anomaly (cataract, coloboma, microphthalmia).

### 149.3.4 Management

**149.3.4.1 Suggested Screening in Children from a Known Family** (developed by Dr Carol Chu, Clinical Genetics, St James's Hospital, Leeds UK, from published data (30,46,47)).

If the family is known to have nevoid basal cell carcinoma syndrome, mutation analysis can be offered if the family is seen and counseled by a clinical geneticist. If a mutation is found in an affected family member, a pre-symptomatic test may be offered to children after appropriate counseling. In a family with a known mutation, if the gene test does not show a mutation in the child, then no further surveillance needs to be undertaken. In a family with a known mutation, if a gene test shows the same mutation in an at-risk family member, then the following screening is recommended:

- Sun avoidance.
- As sun avoidance leads to vitamin D deficiency and sub-optimal levels are generally common in healthy people around the world (48) and specifically in patients with this syndrome (49), supplementation with vitamin D is desirable to achieve levels in the range 60 nmol/L to 85 nmol/L. It is difficult to predict levels therefore measurement may be indicated.
- Baseline chest, skull and spine X-ray.
- Echocardiogram.
- Annual dental screening including orthopantomogram from 8 years.
- Annual skin examination by dermatologist from puberty.
- Six monthly neurological examinations from birth to 3 years and then yearly until age 7 years to promote the early detection of medulloblastoma.

If no mutation is found in the family then at-risk children should have the screening as suggested in the section below as for families with suspected nevoid basal cell carcinoma syndrome.

**149.3.4.2 Investigation in Cases of Suspected Nevoid Basal Cell Nevus Syndrome with No Family History.** In a child who presents with jaw cysts:

- If single cyst and no minor criteria, observe only.
- If more than one cyst:
  - Family history taken.
  - Clinical examination noting clefting or eye abnormalities.
  - Head circumference measurement.
  - Skin examination.
  - Examination of palms and soles of feet for pits.
  - Baseline chest and spine X-ray.
  - Baseline skull X-ray.

- If no abnormalities on tests above, 2 yearly dental screening until 16 years and repeat clinical examination and skull X-ray at 12 years and 20 years.
- If abnormalities at baseline screen or 12 or 20 year screen consistent with diagnostic criteria refer to clinical genetics for full family assessment and possible mutation analysis.

**149.3.4.3 Treatment.** Jaw cysts are excised conservatively except after local recurrence where a more aggressive excision is carried out including removal of a cuff of bone. Basal cell nevi on the skin are observed, but basal cell carcinomas are removed as is usual using cryosurgery, excision, photodynamic therapy (PDT) or Moh's surgery for extensive tumors.

The treatment of cutaneous lesions was reviewed most recently by Lo Muzio and van der Geer (50,51). Radiotherapy must be avoided wherever possible, as affected patients are very sensitive to ionizing radiation; most visibly as the development of more numerous and more aggressive BCC (52) but probably also in other sites (27). Alternate therapies for patients with extensive tumors include photodynamic therapy (53) and most encouragingly for patients with very advanced disease, resolution of multiple tumors has been reported after use of a small molecule inhibitor of the Hedgehog signaling pathway via interaction with Smoothened (54).

#### 149.4 BAZEX-DUPRE-CHRISTOL SYNDROME

This very rare syndrome is a disorder of the hair follicle. The condition was first described by Bazex (55) and has remained most common in France (56). Affected children have hypotrichosis (thin and abnormal hair) (Figure 149-4) and milia (Figure 149-5). Subsequently, deep and lax hair follicles become obvious particularly on the dorsae of the hands (known as follicular atrophoderma) which have been likened to “ice-pick marks” (57)

**FIGURE 149-4** Hypotrichosis in the Bazex–Dupre–Christol syndrome.

(Figure 149-6). Hypohidrosis is a feature, and in a family previously reported by Gould and Barker (58) we have reported the occurrence of hidradenitis suppurativa and the development of multiple perineal trichofolliculomata (59), emphasizing that the pathology in this condition is indeed centered on the hair follicle. In one large pedigree, the clinical picture was recognizably more severe in males (60) although the authors have not seen this in the two families in their care. The early development of multiple basal cell carcinomas in sun exposed areas is a key

**FIGURE 149-5** Milia on the knee of a two-year-old with Bazex–Dupre–Christol syndrome.

**FIGURE 149-6** Follicular atrophoderma on the dorsum of the hand of an adult with Bazex–Dupre–Christol syndrome.

component of the syndrome, but for affected families the phenotypic effects on hair growth and the skin in general are often more symptomatic. The age of onset of the BCC is variable between and within families, from early childhood to middle age. The cell of origin of BCC overall remains controversial but the association of BCC with the Bazex–Dupre–Christol syndrome, which is clearly a disorder of the hair follicle, supports the view that BCC may arise from the hair follicle. Inheritance of Bazex–Dupre–Christol syndrome is by the X-linked dominant route (60), and the gene has been mapped to Xq24–27.1 (61). The critical interval has been recently narrowed to an 11.4Mb interval which includes 101 genes (57).

#### 149.4.1 Non-Syndromal Familial Basal Cell Carcinomas

There are sporadic reports of familial clustering of multiple basal cell carcinomas (62) without the characteristic features of either the nevoid basal cell carcinoma or Bazex–Dupre–Christol syndromes, which may result from the inheritance of as yet unidentified highly penetrant susceptibility genes, or possibly the inheritance of multiple lower penetrance genes in individuals who have had a significant amount of sun exposure.

### 149.5 SQUAMOUS CELL CARCINOMA

#### 149.5.1 Epidemiology

Squamous cell carcinoma (SCC) is a malignancy derived from the epidermal keratinocyte. Most are postulated to result from excessive sun exposure and there is a linear relationship between cumulative lifetime exposure to ultraviolet (UV) radiation and the development of squamous cell carcinoma. Chronic inflammation/ulceration is causal occasionally, the human papillomavirus may predispose and carcinogens are also important, albeit much less frequently. Sir Percival Pott recognized this first, describing an increased incidence of scrotal cancer in chimney sweepers due to chronic exposure to coal tar products.

A study from New Hampshire reported a 235% rise in the incidence of squamous cell cancers in males and a 350% rise in squamous cell carcinoma in females between 1979 and 1994, with 1994 figures at 97/100,000/year for males and 32/100,000/year for females (6). This increase in incidence has been seen in white populations at many latitudes and was attributed to sun exposure and iatrogenic immunosuppression (which increases susceptibility to skin cancer) (56,63). A Swedish study reported in 2003 confirmed this increased incidence, with time showing a strong cohort effect which they attributed to intentional sun bathing. Clustering in families indicates the role of genetic susceptibility, and the study reported familial standardized incidence ratios of 2.25

(95% CI 1.93–2.59) for exposed sites and 2.60 (95% CI 1.38–4.20) for usually covered sites (64).

One squamous cell carcinoma is seen for every three or four basal cell carcinomas in a healthy population. However, this ratio is reversed in individuals receiving therapeutic immunosuppression after organ transplantation, so that squamous cell carcinoma is more common in this group than is basal cell carcinoma (65,66). This observation would suggest that a degree of immunosurveillance is operative in the skin and that this is more important for squamous cell carcinoma than for basal cell carcinomas, although the incidence of both is increased in immunosuppressed patients. The human papillomavirus (HPV) also has a role in SCC carcinogenesis as evidenced in epidermodysplasia verruciformis (EV) described below, and by the identification of epidermodysplasia verruciformis HPV subtypes as a risk factor for skin cancer in immunosuppressed renal transplant patients (67). It is clinically apparent in transplant recipients that sun exposure and latent infection with some HPV subtypes cooperate in SCC carcinogenesis (68) but a causal role for HPV in SCC remains controversial, see review (69).

A number of rare genodermatoses predispose to squamous cell carcinoma and in these syndromes SCC tends to develop earlier in life than in the sporadic variety, as discussed below.

#### 149.5.2 Clinical Features and Pathology of Squamous Cell Carcinoma

Squamous cell carcinomas (SCC) arise predominantly on sun-exposed skin in white skinned outdoor workers, although they may also occur in chronically inflamed skin or scars (Figure 149-7). Males have therefore been affected more frequently than females in the past but, with increasing recreational sun exposure and a decrease

**FIGURE 149-7** Squamous cell carcinoma on the dorsum of the hand in a patient with damage resulting from chronic sun exposure.

in the number of males occupationally sun-exposed, the incidence is now becoming more equal between the sexes. SCC may arise on sun-damaged skin *ab initio* or may arise on in situ disease (Bowen's disease) or sun induced precursors, called actinic keratoses. Actinic keratoses are small scaling or crusted lesions which arise on sun-damaged skin. The exact risk of malignant change in these actinic keratoses is debated, but is of the order of 1–16% per year (70).

The clinical appearance of the classic SCC is that of a non-healing nodule on any body site. Ulceration is relatively common, and the history is frequently that of months or even years of slow growth. Although SCC can be suspected on clinical grounds, a diagnostic excision is usually essential to confirm the clinical impression. The pathology is that of invasive tongues of epidermal keratinocytes which show varying degrees of dedifferentiation and invasion into the underlying dermis. For most tumors surgery is curative, although metastases may occur from primaries which are very thick, arise in particular sites such as the ear and lip, or when the tumor arises in scar tissue and especially in the immunosuppressed.

### 149.5.3 Management

Management of SCC is preferably surgical although radiotherapy may also be used.

### 149.5.4 Genetics of SCC

There is individual variation in susceptibility to SCC. Fair skinned people are more susceptible, and an extreme of this is seen in people with oculocutaneous albinism who are very susceptible to SCC, especially when they live at low latitudes. In most populations, fair skin associated with red hair and freckles is the principal phenotypic marker of risk of SCC, as for other forms of skin cancer. This phenotype is in turn controlled by the pigmentation genes and these are clearly the most important low penetrance susceptibility genes in terms of prevalence. Thus, genes which control the quantity and sub-cellular localization of melanin in the skin are important, such as polymorphisms in the oculocutaneous albinism gene *OCA-2* (71). Also influential are genes which control the ratio of eumelanin to pheomelanin produced, namely variants in the melanocortin receptor gene *MC1R* (10,12,72). Polymorphisms in the *IRF4* gene (15,73) and *SLC45A2* gene (14,16) have also been associated with SCC risk. Both of these genes influence pigmentation, however the additional role of *IRF4* in the immune response may contribute to its role in susceptibility to SCC (15). There are some candidate gene studies reported, for example there is some interest in genes coding for detoxifying enzymes (74) as susceptibility genes but the data are as yet preliminary (75,76). DNA repair genes are obvious candidate susceptibility genes, and a number of studies are emerging in which

this has been addressed (77–80). The vitamin D receptor polymorphisms *Bsm1* and *Fok1* are reported to be associated with risk (81), presumably by modifying cell responses to vitamin D. This risk interacts with vitamin D intake for *Bsm1* polymorphisms (81). Genome wide association studies will further assist in identification of relevant genes associated with SCC.

There are in addition a number of rare hereditary conditions predisposing to squamous cell carcinoma of the skin which we will discuss below:

- Xeroderma pigmentosum
- Self-healing epithelioma of Ferguson Smith
- Epidermodysplasia verruciformis
- Dystrophic epidermolysis bullosa (Hallopeau–Siemens type)
- Porokeratoses

The incidence of non-melanoma skin cancer is also increased in additional genetically determined conditions, which will not be described further such as those listed in Table 149-1.

In terms of somatic genetic events, in both actinic keratoses and squamous cell carcinomas, there is clear evidence of mutation of the *p53* gene (82), which is present in nearly half of tumors (83–85). The function of wild type *p53* is to prevent progress of cells into the cell cycle and thus allow time for unscheduled DNA repair post-UV exposure. Without this checkpoint, cells with ultraviolet (UV) induced signature mutations, (frequently C-T and CC-TT mutations) proliferate and predispose to both actinic keratoses and subsequently to squamous cell carcinomas (82). Mutations with the typical UV signature are also seen in *HRAS* particularly in SCC developing in psoriatics treated with PUVA light treatment (86). Allelotype studies show numerous abnormalities of chromosomes 3p, 9p, 13q, 17p and 17q (38,87). There is some evidence that loss of the 9p tumor suppressors at the *CDKN2A* locus also plays a role in SCC carcinogenesis, as loss of heterozygosity and loss of the entire of 9p are frequently observed in SCCs (88,89). However, conflicting results from immunohistochemical studies of p16<sup>INK4</sup> expression (reviewed by Boukamp et al. (90)) demonstrate that the role of *CDKN2A/p16<sup>INK4a</sup>* in the development of SCCs is currently not understood. The complex karyotype found in SCCs is not found in BCCs, suggesting UV exposure is not the only cause (90).

## 149.6 XERODERMA PIGMENTOSUM

Xeroderma pigmentosum (XP) is one of a group of diseases characterized by defective DNA repair (nucleotide excision repair defects) (91–93), the others being trichothiodystrophy and Cockayne syndrome. There is a remarkable heterogeneity in phenotypes of these syndromes despite a common defect in excision repair. Only patients with classic XP are susceptible to skin cancer (91–93), although patients with trichothiodystrophy are

**TABLE 149-1 Genetic Conditions Predisposing to BCC and SCC**

Condition	Mode of Inheritance	Pathway	Susceptibility
Bazex–Dupre–Christol syndrome	Sex linked dominant	Unknown	BCC
Basal cell nevus syndrome	Autosomal dominant	Hedgehog signaling pathway	BCC
Rombo syndrome	Autosomal dominant	Perhaps DNA repair and/or cell-cycle regulation <sup>a</sup>	BCC
Brooke–Spiegler syndrome	Autosomal dominant	Apoptosis regulation, <sup>b</sup> cell cycle <sup>c</sup>	BCC
Multiple hereditary infundibulocystic BCC	Autosomal dominant	Unknown	BCC
Schopf–Schultz–Passarge syndrome	Autosomal recessive	Unknown	BCC
Xeroderma pigmentosum (groups A to G)	Autosomal recessive	Nucleotide excision repair	BCC, SCC and melanoma
Xeroderma pigmentosum variant	Autosomal recessive	DNA polymerase	SCC
Multiple self-healing squamous epithelioma (Ferguson Smith syndrome)	Autosomal dominant	TGF- $\beta$ signaling <sup>d</sup>	SCC
Epidermodysplasia verruciformis	Autosomal recessive usually but also sex linked and dominant postulated	Unknown but associated with increased susceptibility to viral infection	SCC
Oculocutaneous albinism types 1A, 1B, 1I, 1II and 1IV	Autosomal recessive	Melanin synthesis	SCC
KID (keratitis, ichthyosis and deafness)	Autosomal dominant	Mutation in connexin-26 gene, <i>GJB2</i>	SCC
Dystrophic epidermolysis bullosa	Autosomal recessive	Connective tissue	SCC, small increase melanoma
Junctional epidermolysis bullosa	Autosomal recessive	Connective tissue	SCC
Fanconi anaemia	Autosomal recessive	DNA repair	SCC
Rothmund–Thomson	Autosomal recessive	Chromosomal stability	SCC
Bloom syndrome	Autosomal recessive	Chromosomal stability	SCC
Dyskeratosis congenita (Autosomal dominant and sex linked types)	Autosomal dominant Sex linked	Telomere maintenance	SCC
Werner syndrome	Autosomal recessive	Chromosomal stability	SCC and melanoma
Hermansky–Pudlak syndrome and Hermansky–Pudlak syndrome, type 2	Autosomal recessive	Melanosome and lysosome storage	SCC
Griscelli syndrome (type 1–3)	Autosomal recessive	Pigment granule transport	SCC
Elejalde disease	Autosomal recessive	Pigment granule transport	SCC
Chediak–Higashi syndrome	Autosomal recessive	Lysosome transport regulation	SCC

sun sensitive. Eight subtypes of XP, groups A–H, are characterized by defective unscheduled post ultraviolet (UV) DNA repair of keratinocytes (94,95) and the ninth (xeroderma pigmentosa variant or pigmented xerodermod) is a defect of post replication UV repair (96). XP is inherited as an autosomal recessive disease and is characterized by rapid development of persistent erythema in the first year of life when the child is exposed to ultraviolet radiation. If sun protection is not introduced, premature aging of the skin is followed by the development of malignancy in the first decade (97). Progressive neurological degeneration occurs in a number of patients, specifically those with subtypes A, B, D and G (98).

The loci of the XP genes and their function are itemized in Table 149-2. Groups A–G range from individuals with the most defective DNA repair in group A to the least defective in group G (99). XP is more common in the Middle East and in Japan than in Europe and the United States (100).

### 149.6.1 Clinical Features

Affected individuals may be diagnosed during their first year of life because of the observation that exposure to natural sunlight gives rise to persistent and prolonged erythema. If not protected from further UV exposure,

**TABLE 149-2** Clinical Variants of Xeroderma Pigmentosum and Genes Responsible

Type	Gene Symbol	Chromosomal Locus	Role of Gene in DNA repair

the affected child will have mottled, dry skin similar to that found on sun-exposed areas of an elderly person, with extensive freckling. Before the introduction of rigorous sun avoidance, these children developed cutaneous malignancies during their first decade. Most serious are melanoma and SCC, and many died of metastatic malignancy before the age of 20.

The introduction of effective sun-screening regimens has brought about a significant change in the outlook for these children. With vigorous sun avoidance, the use of protective clothing, and appropriate sunscreens, these children now live to reproductive age (100,101).

A proportion of patients with xeroderma pigmentosum have both ocular and neurological problems in addition to cutaneous problems. Ocular problems include UV-induced keratitis, retinopathy and UV-induced cataract, while neurological problems may include progressive mental retardation, microcephaly and deafness.

## 149.6.2 Management

Management of families with XP includes a regimen of vigorous sun avoidance. The use of highly protective sunscreens, clothing, sun avoidance and UV protective film on windows is required. There must be careful cutaneous surveillance with excision of all possible early cutaneous malignancies and histological examination. Vitamin D supplementation with monitoring of blood levels to achieve those in the range 60–85 nmol/L is therefore essential. The incidence of squamous cell carcinoma is very high indeed in these families; there is also a higher-than-expected incidence of basal cell carcinoma, malignant melanoma, and vascular tumors (102). Tumors of the tip of the tongue are reported more commonly than would be expected. High dose isotretinoin is reported to prevent new neoplasms in those with multiple skin cancers (103). As progressive neurological abnormalities can occur in a minority, routine neurological examination may be indicated.

## 149.7 MULTIPLE SELF-HEALING EPITHELIOMAS OF FERGUSON SMITH

In 1934, John Ferguson Smith described two large kindreds in Ayrshire in the west of Scotland with a history in several generations of multiple self-healing epitheliomas (104): keratoacanthoma like lesions (Figure 149-8). Affected family members generally developed their lesions after puberty, and onset of the condition may be as late as age 40, or older. The clinical picture is that of the development of many rapidly expanding hyperkeratotic lesions over time, usually on sun-exposed skin. Affected patients are therefore advised to avoid sun exposure without becoming vitamin D depleted. These lesions, despite a pathological picture indistinguishable from invasive squamous cell carcinoma, do not usually progress, but spontaneously regress over a period of weeks or months frequently leaving an unsightly or crenated scar (Figure 149-9). SCC may however occur rarely even in sites associated with greater risk of metastasis such as the anus (Figure 149-10), lip or vulva. The syndrome is rare and therefore data are limited, but there is a view that affected patients are radiosensitive (although the use of radiotherapy has been reported (105)) and therefore that radiotherapy should be avoided.

Family studies indicate clearly that transmission is by autosomal dominant inheritance. The gene for multiple self-healing epitheliomas of the Ferguson Smith type has been mapped to chromosome 9q. Haplotype studies indicated that the disease locus was most likely to lie between D9S29 (9q31) and D9S1 (9q22.1–q22.2) (106), but it took many years to identify the causal gene. It was when it became possible to sequence many hundreds of genes with exon capture using high capacity shotgun sequencers that mutations in the *TGFBR1* gene, (being outside the 4-Mb interval originally proposed (107)), was identified as the

**FIGURE 149-8** Exuberant keratoacanthoma-like lesion on the ear of a patient with self-healing epitheliomas of Ferguson Smith.

**FIGURE 149-9** Crenated scars left on the skin of the nose after spontaneous involution of a keratoacanthoma-like lesion in self-healing epitheliomas of Ferguson Smith.

causal gene. It was established that the families with self-healing epitheliomas of Ferguson Smith had loss-of-function mutations in the same *TGFBR1* gene as underlies Loeys–Dietz syndrome in which condition the mutations are missense mutations. It is surprising (given that this condition was previously supposed to be a founder mutation arising in Ayrshire) that multiple mutations were identified in the *TGFBR1* gene although c.154G>C was the most frequent (107). It may be therefore subsequently prove to be that the syndrome is more common in parts of the world other than Scotland than had been supposed.

**FIGURE 149-10** Anal tumor in self-healing epitheliomas of Ferguson Smith: such tumors are rare in this syndrome but do occur and may in this site behave more aggressively than in other sites in this condition.

### 149.8 EPIDERMODYSPLASIA VERRUCIFORMIS

Epidermodysplasia verruciformis (EV) is a condition in which there is increased susceptibility to infection with the human papillomavirus (HPV) leading to multiple warts, and where particular HPV subtypes are present, also to squamous cell carcinoma. The HPV subtypes associated with EV are now known as betaPV types (108). Unlike high-risk mucosal HPV subtypes which cause cervical cancer, betaPV types do not integrate into cellular DNA and appear additionally to require exposure to ultraviolet light for carcinogenesis (108). A very large number of HPV types may be involved in EV, but types 5 and 8 are the most consistently associated with a risk of developing squamous cell carcinoma. The betaPV HPV types are ubiquitous (being detected in excess of 80% of people without skin cancer), but may then proliferate as a result of loss of immunity when the host is immuno-suppressed either genetically, as in EV or as a result of immunosuppressive drug treatment. There is recent evidence also for a small role for other oncogenic viruses such as the Merkel polyomavirus (109).

Although EV may be acquired, as a result of HIV infection for example (110,111) or haematological malignancies (112), usually it is manifest as a rare, recessively inherited genodermatosis. Recessively inherited EV was mapped to chromosome 2p21–p24 (EV2) and 17q25 (EV1). On chromosome 17, 2 adjacent related genes—*EVER1/TMC6* (113) and *EVER2/TMC8* (114)—were identified. Nonsense mutations in the genes *EVER1* and *EVER2* have been identified in over 75% of cases (115). It is thought that mutations at these loci result in susceptibility to the viral infection as a result of impaired cell-mediated immunity but the precise mechanisms remain

unclear. There are reports of more occasional X-linked inheritance (116,117). A family from India was reported in which the mode of inheritance appeared to be more consistent with a dominant gene although consanguinity is another possible explanation, (118) and more recently a mother and affected sons were reported from Iran (119). A lack of *EVER1* and 2 mutations was recently reported in a family in which EV appeared to be dominantly inherited (115), so that the genetic basis of all cases of EV is not yet understood.

### 149.8.1 Clinical Features

Affected individuals develop large numbers of flat and plane warts, most abundant usually on the face and neck, in childhood. These warts tend to coalesce to form large plaques. Premalignant lesions such as actinic keratoses and Bowen's disease start to develop in the third and fourth decades and squamous cell carcinoma may develop in up to 20% of such lesions, most commonly on sun-exposed sites, implying a role for ultraviolet radiation as a co-carcinogen (118).

## 149.9 RECESSIVE DYSTROPHIC EPIDERMOLYSIS BULLOSA (OF THE HALLOPEAU-SIEMENS TYPE)

Squamous cell carcinoma may complicate different forms of epidermolysis bullosa (EB) (120–122) but the association is particularly with the recessive dystrophic type. This autosomal recessive condition is the most severe variant of dystrophic epidermolysis bullosa (EB), and is due to mutations in the gene *COL7A1* which encodes the anchoring fibril protein of type 7 collagen. This is a very large gene with 118 exons located on 3p21. The Hallopeau–Siemens type of EB is an autosomal recessive disease due to mutations in both alleles of *COL7A1*, leading to reduction in mRNA and impaired synthesis of collagen 7 peptides for assembly into anchoring fibrils (123,124).

Affected infants can be diagnosed at birth by the presence of fragile skin and rapid development of blisters at sites of trauma which then scar. Nails, teeth, hair and oral mucosa are also abnormal. Children with this variant of EB are at greatly increased risk of squamous cell carcinoma, which frequently develops in the second decade on sites of blister-induced scarring. The carcinomas are unusually aggressive and metastasize early, so death results from SCC in 78.7% of affected individuals by the age of 55 years (122). Tumors arise predominantly at the sites of maximal scarring rather than sun exposure (121) and chronic inflammation/continuous wound healing is probably causal. A small study reported no evidence for a role for the human papillomavirus in these patients any more than in SCC occurring in healthy individuals (122). There does not seem to be an excess of non-cutaneous cancer (125) but there is a small excess of melanoma (122). That the tumors behave in a very much

more aggressive way than do sporadic SCC suggests that they are biologically different and although attempts are being made to understand this (126) the nature of these differences is not yet understood.

## 149.10 POROKERATOSES

The term porokeratosis describes a group of disorders of keratinization associated with an unstable clone of keratinocytes which give rise to a characteristic clinical and pathological picture. One variety of this condition, porokeratosis of Mibelli, is inherited by autosomal dominant transmission, and is a precursor to squamous cell carcinoma in 7%–20% of cases. Many tumors in these patients appear to have followed radiotherapy and immunosuppression (127). The gene responsible has been provisionally mapped to the short arm of chromosome 3 (128).

### 149.10.1 Clinical and Pathological Features

Affected patients have large plaques on any body site, characterized by a raised rim and central mildly atrophic epidermis. The characteristic “rim” is reflected in the pathology which shows a raised so-called cornoid lamella with loss of granular layer and parakeratosis around the edge of the lesion.

## 149.11 MUIR–TORRE SYNDROME

Patients with the autosomal dominant hereditary non-polyposis colon cancer syndrome (HNPCC) may also develop skin cancers, and this sub-type, or phenotypic variant of the HNPCC syndrome is known as the Muir–Torre syndrome (129). The syndrome is defined by a combination of sebaceous tumors of the skin and one or more internal malignancies, most often colon cancer. The types of skin tumor classically include sebaceous adenoma, sebaceous epithelioma, sebaceous carcinoma, and keratoacanthoma (130,131) but may also include actinic keratoses and squamous cell carcinomas. HNPCC is characterized by germline mutations of DNA mismatch repair genes (including *bMSH2*, *bMLH1*, *bPMS1* and 2, *bPMS* and *bMSH6*) (129), and corresponding microsatellite instability may be demonstrated in resected skin tumors from Muir–Torre families. Germline mutations in the HNPCC associated mismatch repair genes, particularly *bMSH2* (130) (not so far in *bPMS1* or 2), have been reported. It is said that a family history consistent with the Muir–Torre syndrome should additionally be excluded when patients have multiple non-sebaceous tumors, tumors in relatively sun-protected sites or tumors occurring in people who also have sebaceous hyperplasia (129), but the validity of this is unclear.

Where skin tumors suggestive of Muir–Torre syndrome occur with no personal or family history of HNPCC, the genetic basis and indeed the risk of visceral tumors in the future is difficult to assess. It is reported however that

sebaceous tumors overall are associated with Muir–Torre syndrome in only 14% of cases (132). Screening tumors for microsatellite instability (by immunohistochemistry) or colonoscopy may be appropriate but advice from genetics services may be the best way to proceed.

## 149.12 MELANOMA

Melanoma is responsible for the great majority of skin cancer deaths. The incidence has increased dramatically in the United States, the United Kingdom and Australasia during this century (133). The highest rates currently occur in New Zealand (134,135). The rate of increase has been faster than for any other malignancy with the exception of lung cancer in women, but there is evidence of a leveling off in incidence in some countries (135), but not in others (136).

Melanoma is predominantly a cancer of people who have skin which tends to burn, and higher incidences occurring where pale-skinned peoples live in hotter countries indicates that sun exposure is the main cause. Rare cases occur however in all skin types in sun-protected sites such as the sole of the foot, under the nail or on genital skin, and the etiology of these rarer subtypes is as yet unclear. The type of sun exposure which is causal for the majority of melanoma however has been controversial, but there is clear evidence for a role of intermittent sun exposure resulting in sunburn (137,138). This increased incidence has therefore been attributed to intense sun exposure on holiday in white skinned (and therefore vulnerable) peoples. A current hypothesis however is that there may be two routes to the development of melanoma, via acute, intermittent sun exposure (for which increased numbers of melanocytic nevi are a risk factor) and via chronic cumulative overexposure (139,140). Evidence for this ‘two route’ hypothesis has come from molecular studies in primary tumors, which have suggested that mutations in the *BRAF* gene (141) typify superficial spreading melanomas which arise on intermittently sun-exposed body sites and for which melanocytic nevi are a risk factor, but are much less common in melanomas arising on chronically sun-exposed or in non-sun-exposed sites (142). Melanomas are therefore genomically complex and although common inherited susceptibility genes have been identified, the relationship between these genes and the genomically different primary tumors remains unclear.

### 149.12.1 Clinical Features and Pathology

Melanoma commonly arises from benign proliferations of melanocytes: melanocytic nevi, or moles, but it may arise from normal appearing skin. Most commonly the tumor grows horizontally in the epidermis for some time (radial growth phase) before growing vertically (vertical growth phase). There are different clinico-pathological subtypes of melanoma which start as radial growth phase.

FIGURE 149-11 Superficial spreading melanoma.

The commonest is the superficial spreading melanoma (Figure 149-11). Lentigo maligna is a variety seen most commonly on the face and acral lentiginous melanoma on the hand or foot. The nodular melanoma appears to go into vertical growth phase from the beginning, although in some tumors the radial growth phase is probably just destroyed by the growing vertical phase tumor (Figure 149-12). It is thought that the progression from benign nevus through atypical nevus (dysplastic nevus), radial growth phase melanoma to vertical growth phase is a continuum in which multiple genetic events occur: in a similar way to that described in the colon as the tumor evolves from a polyp.

### 149.12.2 The Genetics of Susceptibility to Melanoma

The most common genetic determinants of susceptibility to melanoma (and non-melanoma skin cancer) are the skin pigmentation genes, as melanoma is predominantly a cancer of white skinned peoples. Thus genes which produce darker skin are protective, and therefore the genes which govern the amount of melanin produced by melanocytes and the way that melanin is packaged in the skin are major determinants of susceptibility. Additional genes control the type of melanin produced. The *MC1R* gene, for example, codes for the melanocortin receptor to which melanocyte stimulating hormone (MSH) binds, and *MC1R* variants exist which modulate the ratio of black pigment (eumelanin) to red pigment (pheomelanin) produced in response to MSH. These variants increase the amount of red pigment produced and therefore

**FIGURE 149-12** A friable nodular melanoma difficult to distinguish from other forms of skin cancer.

inheritance of these results in red hair and fair skin (72), and freckles (143), all of which are risk factors for melanoma (144) and skin cancer in general. These *MC1R* variants are established as melanoma susceptibility genes (145,146) even in the presence of dark hair (147). In terms of common low penetrance melanoma susceptibility genes, *MC1R* variants are the first genes clearly identified as significant. A number of small, candidate gene studies have been reported which have provided some evidence of association with melanoma risk but these are difficult to evaluate and therefore will not be listed here. GWA has now identified 11 susceptibility genes (including confirming the role of *MC1R*) (Table 149-3). These genes include pigment genes, genes associated with increased numbers of nevi and additional genes not associated with a particular phenotype (see Table 149-3). The genes of biological interest include *CASP8* (which is in an apoptosis pathway) and the ataxia telangiectasia gene *ATM* (Barrett et al. (2011)—submitted).

**149.12.2.1 Melanoma in Family Cancer Syndromes.** The majority of families in which melanoma clusters are at increased risk of melanoma alone or melanoma and pancreatic cancer and the genetic basis of these susceptibilities is discussed below.

Melanoma does, however, also occur in other genetically determined family cancer syndromes. Melanoma is a second malignancy for example in familial retinoblastoma, accounting for a proportion of second malignancies in affected individuals occurring particularly in the radiation field (148). A cohort study was reported in

1993 in which a statistically significant excess of mortality was demonstrated from melanoma in retinoblastoma survivors (149). Anecdotal reports of both retinoblastoma and melanoma in families have been made (150), but a cancer registry review showed no increased risk of melanoma in parents of affected children (151).

There is thought to be an increased risk of melanoma in families with the Li-Fraumeni syndrome (152), in which the majority of cancers are sarcomas, brain tumors or bilateral breast cancers, and which are attributed to inherited mutations in the gene *p53*. Certainly a registry study from Sweden showed an increased risk of childhood osteosarcoma in children of mothers with melanoma (153) and there is an excess of melanomas in survivors of childhood soft tissue sarcomas (154), but as for all second cancers it is difficult to differentiate genetic from treatment effects.

Melanoma is also reported to occur in a relatively small proportion of families with an increased risk of bowel cancer due to inherited mutations in mismatch repair genes (hereditary non-polyposis coli) (HNPCC). In one recent series, nine family members from eight families developed melanoma in a series of 60 with HNPCC (155).

Melanomas have been described in the Birt-Hogg-Dube syndrome (156) and in one report these were multiple desmoplastic melanomas (157). We have seen acral lentiginous melanoma in one case in Leeds, but the strength of the association is unknown. Birt-Hogg-Dube syndrome is a rare genodermatosis in which there are hair follicle hamartomas on the face, renal cancer, and lung cysts associated with pneumothoraces (158). The syndrome is associated with germline *FLCN* mutations (159) which code for a putative tumor suppressor gene called folliculin.

**149.12.2.2 High Penetrance Genes/Familial Melanoma.** Progress has been made in understanding rare, high penetrance, susceptibility genes by studying families with multiple cases of melanoma but without the above listed cancer family syndromes. This progress has resulted from work carried out by many groups around the world and as a result of the activities of the Melanoma Genetics Consortium ([www.genomel.org](http://www.genomel.org)).

Approximately 5% of melanoma patients have a clear history of melanoma in a first-degree relative. Patients in multiple case melanoma families present with their first primary melanoma on average two decades earlier than sporadic cases, and have a higher than expected incidence of multiple primary melanomas. As with sporadic melanomas, the commonest subtype is the superficial spreading melanoma.

An early study on 14 US families with both familial melanoma and also large numbers of atypical or dysplastic nevi suggested that a melanoma susceptibility gene was located at chromosome 1p36 (160), but this report has not been confirmed, and no candidate gene has emerged.

Forty percentage of the families with three or more cases of melanoma carry causal mutations in the

**TABLE 149-3 Low Penetrance Susceptibility Genes Identified for Melanoma from Genome-wide Association Studies**

Gene	SNP	Risk of Melanoma for Each Allele <sup>i</sup>	Associated Phenotype	References of Studies also Showing Association

*CDKN2A* gene at 9p21 which codes for a cell cycle control protein called p16. This protein binds to and inhibits the cyclin-dependent kinase 4 (CDK4). 9p21 is deleted in a high proportion of melanoma cell lines (161) and *CDKN2A* is also an important suppressor gene in other malignancies, particularly in pancreatic cancer (162). The gene is composed of two exons (1 $\alpha$  and 2) which code for p16 and one alternatively spliced exon (exon 1 $\beta$ ), which codes for a completely unrelated protein called p14ARF. Insertions, deletions and missense or nonsense mutations have all been recorded in *CDKN2A* in familial melanoma patients in all three exons of the gene, and functional studies have confirmed the loss of suppressor activity in a proportion of these mutations. Some mutations impact on p16 alone, some on p14ARF alone (2–3% of families overall) (163,164) and others on both, but in all families the susceptibility is predominantly to melanoma. GenoMEL maintains a data base of these mutations (eMelanobase) which is now part of LOVD (Leiden Open Variation Database) <http://chromium.liacs.nl/LOVD2/home.php>.

A number of founder mutations in *CDKN2A* have been reported. p.M53I mutations appear to be particularly common in Australian and Scottish families, but not in US families. Table 149-4 summarizes mutations

found across families in Australia, Europe and North America in a GenoMEL study reported by Goldstein et al. (164). The percentage of families investigated who have *CDKN2A* mutations ranges from 20% to 50% depending on geographical location with an overall prevalence of 38% in 465 families (164). In general, families with three or more affected family members have a higher incidence of mutations. In lower incidence areas such as Italy, the proportion of two case families with identified mutations is higher than elsewhere (165). A high proportion of melanoma families have family members with multiple primary melanomas, and *CDKN2A* mutations have also been reported in patients with multiple primary melanomas who have no identifiable positive family history of melanoma (166). A possible gene environment interaction is suggested by the observation that the incidence of melanoma in families with the 9p21 mutation has increased 21-fold since 1952, and the suggested reason for this increase is greater exposure to ultraviolet radiation (167), although there may be some biases here. A consensus statement published following a review of the available literature stated that, except in regions of high melanoma incidence, for example Australia, higher rates of *CDKN2A* mutation are found in those with three or more primary invasive melanomas and/or families with at least one invasive melanoma and

Goldstein, A.; Chan, M.; Harland, M., et al. High-Risk Melanoma Susceptibility Genes and Pancreatic Cancer, Neural System Tumors, and Uveal Melanomas Across GenoMEL. *Cancer Research* 2006, 66, 9818–9828.

two or more other diagnoses of invasive melanoma and/or pancreatic cancer among first or second degree relatives on the same side of the family (168). Individuals who satisfy these criteria will benefit most from genetic counselling and possible testing, although the value of clinical testing is debated (169,170).

Rare families have been described in which susceptibility appears to be due to inherited mutations in the *CDK4* gene at the p16 binding site. Worldwide, only 2% of families have been reported with a *CDK4* mutation (164). This is clearly excessively rare in melanoma families, but does appear to be mutated in some of the families originally reported as having chromosome 1 abnormalities. This gene maps to chromosome 12q14 and the mutant acts as a dominant oncogene by preventing inhibition by wild type *CDKN2A* (171,172).

The fact that not all melanoma families investigated show *CDKN2A* or *CDK4* mutations suggests that other melanoma susceptibility genes exist, and a number of families have been identified linked to 9p21 who do not currently have identifiable *CDKN2A* mutations, implying the presence of a possible second tumor suppressor gene near this locus. Strenuous efforts are being made to identify the “missing” genes.

A high proportion of melanoma families also have large numbers of melanocytic nevi which are clinically and pathologically atypical—so-called dysplastic nevi (173) (Figure 149-13). These nevi are larger than banal benign nevi, and may have an irregular edge and histological evidence of a stromal reaction. They reflect the increased proliferation seen in melanocytes in at-risk individuals after sun exposure. Although it was initially suggested that only those members of melanoma families with such nevi were at risk of melanoma, other studies have shown that this is not the case and that family

members with a normal complement of banal melanocytic nevi may also be *CDKN2A* mutation carriers with associated melanoma risk (174).

In some geographical areas of the world (not in Australian (164) and UK families to date at least) inherited *CDKN2A* mutations also increase the risk of pancreatic cancer (175–177), although clustering of both cancers may occur also in families without such mutations (178). A study of Dutch families with melanoma demonstrated a significantly increased risk of pancreatic cancer, cancers of the respiratory system, lip, oral cavity and pharynx, non-melanoma skin tumors and tumors of the eye/brain (uveal melanoma and brain tumors) in patients carrying the p16-Leiden *CDKN2A* mutation (177). There is some further anecdotal evidence for an increase in squamous cell carcinomas of the head and neck, (179) and for sarcoma (180).

### 149.12.3 Management

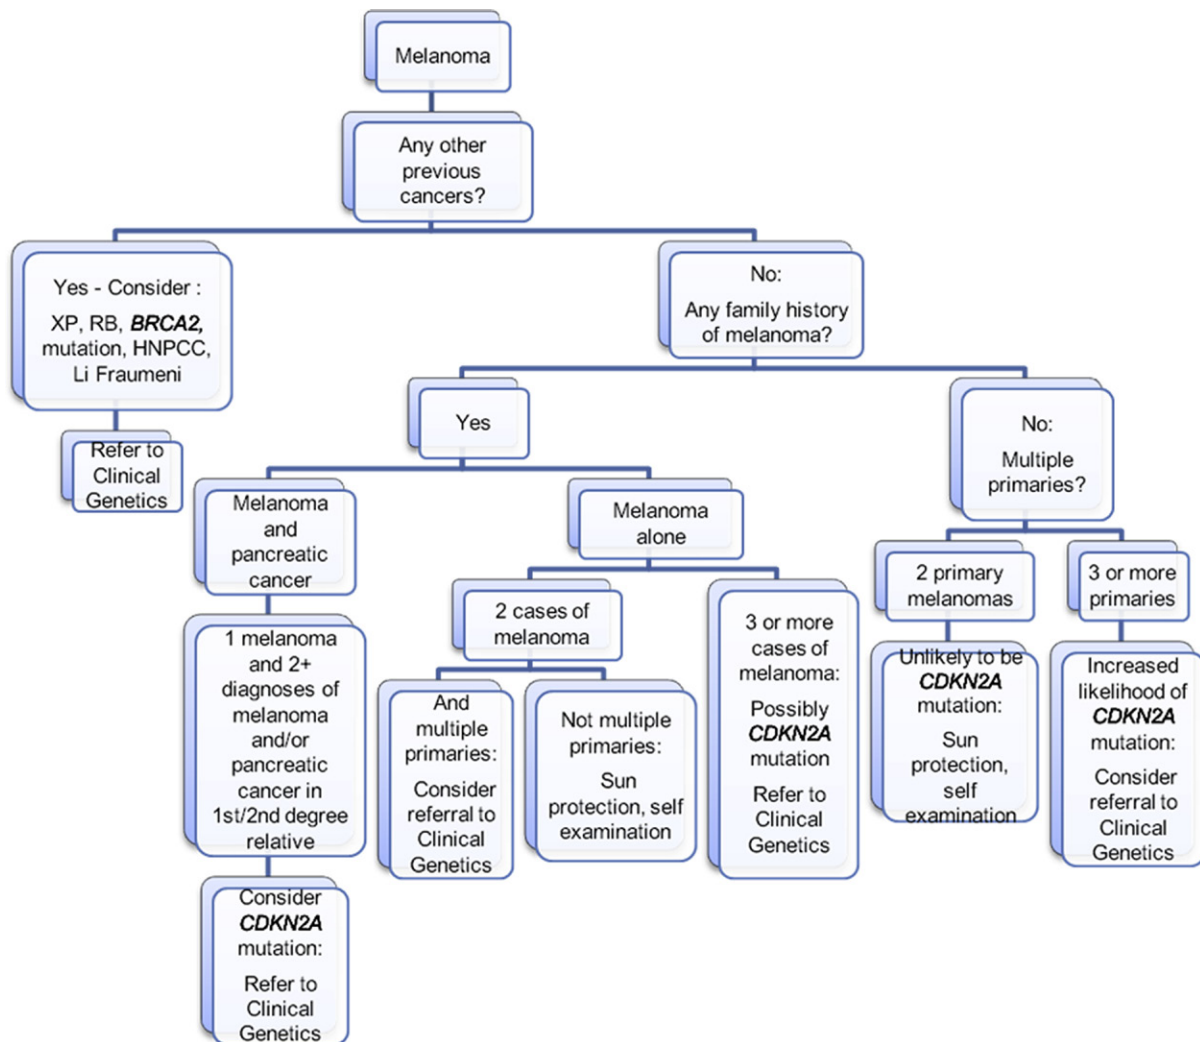

All patients with suspected early melanomas should have a family history taken, and corroborative pathological evidence sought for lesions said to be melanomas in family members. If confirmed, family members should be offered sun protection advice (without inducing vitamin D depletion), a total body skin examination to identify early melanomas or atypical nevi but most particularly, self-examination training.

All suspected melanomas should be excised with a narrow margin of surrounding normal skin and sent for pathological confirmation. The thickness of the tumor measured from the overlying granular layer to the deepest underlying invasive cell will determine whether a wider excision is needed and will also determine the likely prognosis. Consider referral to

**FIGURE 149-13** Multiple nevi in the atypical mole syndrome, associated with risk of melanoma within families at risk of melanoma in the general population.

**FIGURE 149-14** Indications for referral to clinical genetics in cases of malignant melanoma.

clinical genetics for counseling and genetic testing for **CDKN2A** mutations for those individuals with multiple (three or more) primary melanomas, and patients with one melanoma and a family history of two or

more other cases melanoma or pancreatic cancer (168) (Figure 149-14).

Patients in whom a primary melanoma has been excised should be regularly followed-up, particularly

members of melanoma families, as there is a greatly increased risk of second and subsequent primary melanomas in these families. Detailed photography at the first visit of all melanocytic nevi may be useful for identifying subsequent early change in these nevi. Protection from sunburn without inducing vitamin D depletion is crucial, and families with *CDKN2A* mutations should also be advised to avoid smoking given the relationship between smoking and pancreatic cancer.

### Biographies

**Professor Julia Newton-Bishop** is Professor of Dermatology at the University of Leeds, UK. She manages a skin cancer screening service at St James's Hospital in Leeds and leads a research group designed to identify the causes of melanoma and the determinants of survival. She is the chairman of the international melanoma genetics consortium GenoMEL ([www.genomel.org](http://www.genomel.org)) and a new consortium called BioGenoMEL addressing the genetics of melanoma relapse.

**Dr Rosalyn Jewell** is a clinical research fellow and currently a graduate student in Professor Newton-Bishop's research group. She is a career Clinical Geneticist in training. She is in receipt of an MRC Fellowship.

## Psoriasis

*Johann E Gudjonsson and James T Elder*

University of Michigan Health System, Ann Arbor, MI, USA

### GLOSSARY

**Psoriasis** – Chronic inflammatory disease of the skin characterized by red scaly plaques on the body and thought to be autoimmune in nature

### 150.1 INTRODUCTION

Psoriasis is a chronic inflammatory skin disease that affects around 2% of the Caucasian population. The majority of cases arise in individuals younger than 30 years of age, with more than 10,000 cases per year arising in children less than 10 years old (1). The cutaneous manifestations of psoriasis are visibly obvious, with a strong negative impact on quality of life (2). Up to 40% of patients develop an associated arthritis, which can be severe and deforming (3). The disease has a strong genetic component (4) and tends to have a fluctuating course that can sometimes be linked to environmental factors (5). In recent years, considerable progress has been made in unraveling the genetic complexity of psoriasis, mostly through the use of genome-wide association studies, with over 20 susceptibility loci identified to date.

### 150.2 CLINICAL FEATURES AND SUBTYPES

Psoriasis is clinically characterized by erythematous scaly plaques, which are sharply demarcated from normal skin and predominantly located on the scalp and extensor surfaces of the extremities, although in some cases they can involve the entire skin surface. Several different forms of cutaneous psoriasis can be observed in the same person, including chronic plaque, guttate, inverse, seborrheic, and pustular types (Figures 150-1 and 150-2). Although it has been demonstrated that the clinical phenotypes of psoriasis may be genetically determined to a large extent, the clinical manifestations of psoriasis can change over time in any given person (6).

Chronic plaque psoriasis (psoriasis vulgaris) is the most common type of psoriasis, seen in approximately 90% of patients. This is characterized by red, scaly

plaques, sharply demarcated from normal skin, located primarily on the elbows and knees (Figure 150-2). The severity and extent of the disease varies widely from patient to patient, although there is consistently constant production of large amount of scale.

Guttate (drop-like) psoriasis is characterized by eruption of many small (0.5–1.0 cm in diameter) scaly lesions over the trunk and proximal extremities. It typically occurs in young adults and has a strong association with preceding or concomitant streptococcal pharyngitis (7). The eruption is typically self-limited, lasting up to 12–16 weeks, although around one-third to one-half of patients go on to develop chronic plaque psoriasis (8). It has a very strong association to human leukocyte antigen (HLA) variant HLA-Cw6 (9).

Other clinical subtypes of psoriasis are less common. In inverse psoriasis, the lesions are located in the major skin folds such as the axillae, inguinal folds, genital region, and the neck. Scaling is usually minimal or absent. Seborrheic psoriasis is characterized by erythematous plaques with greasy scale localized to seborrheic areas such as the scalp, glabella, nasolabial folds and presteral areas. In the absence of typical psoriasis findings elsewhere, it may be hard to distinguish from seborrheic dermatitis. Several different types of pustular psoriasis exist, including localized, generalized, and palmoplantar pustulosis. Generalized pustular psoriasis can present abruptly with high fevers, diffuse redness, and waves of pustules on the skin and is the only form of psoriasis that can be life-threatening.

Finally, erythrodermic psoriasis is the generalized form of the disease that affects all body sites, including the face, hands, feet, trunk, and extremities. Instead of thick, adherent, white scale there is diffuse erythema with superimposed fine scale. Patients tend to lose excessive heat because of generalized vasodilation and this can lead to high-output cardiac failure.

Nail changes are frequently observed in psoriasis and are found in up to 40% of patients. Several distinct changes have been described and these correlate with age, duration, and extent of disease, and with the presence of psoriatic arthritis (10).

**FIGURE 150-1** Chronic plaque psoriasis—the most common form of psoriasis (A, B, C, D). It is characterized by red, scaly lesions, sharply demarcated from normal skin. Psoriatic lesions are most commonly located on the extensor surfaces of the extremities, such as the knees and elbows, but can involve any part of the skin. With extensive involvement, or localized such as on the hands and feet (C and D), it can be severely debilitating.

Psoriatic arthritis is a common manifestation of psoriasis seen in 10–40% of patients (3,11). Psoriatic arthritis is rheumatoid-factor negative and usually presents a few years after the onset of skin disease, between the ages of 35 and 45 years (12). It has a prominent genetic component and several different subtypes have been described, as originally defined by Moll and Wright (13). These subtypes involve distal interphalangeal arthritis of the hands and feet, symmetric polyarthritis, symmetric oligoarticular arthritis, predominant axial spondylitis, and/or arthritis mutilans. The clinical subtype of psoriatic arthritis is not fixed and the clinical manifestations in any given patient have been shown to change considerably over time (14).

### 150.3 PREVALENCE, AGE AT ONSET AND SEX RATIO

Psoriasis is found worldwide, although its frequency varies widely among different ethnic groups, with reported prevalence ranging from 0 to 11.8% (15). The reasons for this wide range in prevalence ratios are multiple. Many of these studies had several confounding variables, most notably the method of ascertainment (clinic-based or population-based, examination-based, or questionnaire-based). Nevertheless, examination of available population-based studies show prevalence ranging from 0.2 to 4.8%, with the average for northern Europe being around 2% (16) and in the United States ranging from 2.2

to 2.6% (17). Incidence of psoriasis is lower in Asians, around 0.3 (18) to 1.2% (19), and in a population-based examination of more than 12,500 Samoans and 26,000 South American Indians, not a single case of psoriasis was observed (20). Based on several small investigations from Africa there appears to be a difference in prevalence of psoriasis in East Africans (2.0%) versus West Africans (0.3%) (20a), potentially explaining the low frequency of psoriasis in African-Americans, most of whom originated from West Africa (17).

Prevalence of psoriatic arthritis varies widely between studies, ranging from 0.04 to 0.4% (3). A recent population-based survey determined that the prevalence of psoriatic arthritis in the United States is 0.25%, with 11% of psoriasis patients having concomitant arthritis (11).

Psoriasis is equally common in males and females (20a,21) and there is no evidence for clinical differences between males and females (16). It may first appear at any age, from birth to the eighth or ninth decade, although it is most likely to appear between the ages of 15 and 30 years (16). Age of onset correlates with HLA-Cw6 carriage (22) and with a higher likelihood of positive family history, and this was the major reason for the previously used classification of psoriasis into type I and type II disease, with type I having strong association with HLA-Cw6 and onset before the age of 40 years, and type II onset after the age of 40 and lacking HLA associations (22a).

**FIGURE 150-2** Different clinical manifestations of psoriasis. Psoriasis can present in several different forms. It can sometimes present as annular plaques (A), or pustular (B), although this presentation is much less common. Some lesions can present with marked hyperkeratosis (C, D). Often with resolving pustular psoriasis, the lesions progress to chronic plaque psoriasis or diffuse erythroderma (E). Nail changes are common in psoriasis and several types of nail changes are recognized, including dystrophy with marked subungual hyperkeratosis (F) and loosening of the nail plate from the nail bed (onycholysis) (G).

#### 150.4 GENETIC EPIDEMIOLOGY

Psoriasis has been appreciated as a genetic disease for nearly 100 years (23). However, only about one-third of patients have an affected first-degree relative (20a). The strongest evidence for the genetic basis of psoriasis was previously provided from twin studies (16). As identical twins have all their alleles in common, in contrast to fraternal twins where the sharing is only about half, if genes play an important role the disease concordance should be greater in monozygotic than dizygotic twins. This is indeed the case in psoriasis, where concordance in monozygotic twins has been shown to range from 35 to 73% in various studies (24). This is about three times higher

than that observed in dizygotic twins (16), and as this concordance is less than 100%, it suggests involvement of environmental factors in addition to genetic predisposition. Interestingly, twin studies have also indicated that many of the clinical features observed in psoriasis are also determined by genetic factors (24a).

Using recurrence risk analysis it has been demonstrated that psoriasis is a polygenic disease. Recurrence risk analysis involves calculating the risk ratio,  $\lambda_r$ . This parameter describes how much more common a disease is in relatives of index case compared with the general population (25). Application of this type of analysis to three major population-based epidemiological studies

(26) demonstrated that the excess recurrence risk of psoriasis for relatives of degree  $r$  dropped by a factor of 6–7 as  $r$  increased from 1 to 2, as opposed to the factor of 2 predicted for monogenic disorders (27), indicative of polygenic inheritance. In accordance with such a model, the risk of psoriasis in an offspring has been estimated to be 41% if both parents are affected, 14% if one parent is affected, and 6% if one sibling is affected, compared with 2% when no parent or sibling is affected (28).

Twin studies and pedigree studies have also been used to calculate the heritability ( $h^2$ ) of psoriasis, which measures the proportion of the variability of a multifactorial trait that is due to genetic factors. Various estimates have calculated this to be in the range of 52–90%, which is among the highest of any multifactorial disorder (20a,27).

The only study to analyze concordance of psoriatic arthritis in twins found a concordance rate of 10% in monozygotic versus 3.7% in dizygotic twins, lower than that observed for cutaneous psoriasis (24d). However, this study was far too small to draw definite conclusions. Importantly, numerous other studies have reported familial aggregation of psoriatic arthritis (29) and the risk for affected first-degree relatives ( $\lambda_1$ ) is in the range of 25–55 (24d,30) which is substantially higher than that observed for cutaneous psoriasis (ranging from 4 to 10) (27).

Parent-of-origin effects have also been proposed for psoriasis and psoriatic arthritis (31). In one study, the birth-weight of children of parents with psoriasis was found to be influenced by the sex of the parent with psoriasis, with offspring from fathers with psoriasis being heavier than children from mothers with psoriasis (32). Excessive paternal transmission in psoriatic arthritis has been described (33), consistent with the findings of a linkage study showing predominant transmission of an allele of paternal origin on chromosome 16 (34).

## 150.5 ENVIRONMENTAL FACTORS

Multiple environmental factors have been implicated in the pathogenesis of psoriasis (16) and the impact of these factors is demonstrated by the less-than-perfect disease concordance in monozygotic twins, as discussed earlier. The specific roles of the various environmental factors are likely to differ, with some being important in triggering the disease while others exacerbate or modify the disease (16). Streptococcal throat infections are the best characterized environmental factor in psoriasis (35) and have been shown to both trigger the disease as well as exacerbate preexisting chronic plaque psoriasis (36). The first report of this association was made in 1916 (37) and has since then been confirmed in multiple studies (7,8). Interestingly, primary skin infections by streptococci generally do not trigger or exacerbate psoriasis (16). The association of streptococcal throat infections and HLA-Cw6 is of particular interest as it has been

hypothesized that psoriasis is caused by cross-reactive epitopes between human skin keratins (KRT16 and KRT17) and streptococcal M-protein, a rod-like extracellular virulence factor of streptococci with sequence homology to epidermal keratins (35). Consistent with this hypothesis, skin homing CD8+ T-cells taken from HLA-Cw6+ patients have been shown to respond to antigens common to both KRT17 and M-protein, whereas non-psoriatic HLA-Cw6+ controls respond only to the M-protein peptides (38). Another line of evidence for this mechanism is that T cells carrying the same T-cell receptor gene rearrangement have been identified in the tonsils and lesional skin of psoriatic patients (39). This would suggest that in genetically susceptible (HLA-Cw6+) individuals, T cells react against streptococcal antigens in the tonsils and subsequently home to the skin where they encounter cross-reactive KRT17 and KRT16 derived antigens. Thus guttate and streptococcal-induced psoriasis may be caused by cross-reactive T-cells activated by streptococcal infections of the tonsils, whereas in chronic plaque psoriasis inflammation is maintained by autoreactive T cells that continue to respond to keratin peptides long after the streptococcal infection has been cleared (16,40).

HIV infection has been associated with severe active psoriasis (41). However, the prevalence of psoriasis in HIV infection is about the same as in the general population (~2%) (42), suggesting that HIV infection is not a trigger but a modifying factor in psoriasis. Thus as the immunodeficiency in HIV progresses, psoriasis gets progressively more active and severe, but interestingly, remits in the terminal phase (43). Likewise, with active antiretroviral treatment, psoriasis improves (44). This exacerbation has been speculated to be due to loss of regulatory CD4+ T cells and subsequent uncontrolled increase in the activity of the CD8+ T-cell subset (40,45). Consistent with this scenario, other autoimmune diseases that are CD8+ T-cell driven predominate in HIV (45). Another possibility is that the HIV virus has a more direct role in the pathogenesis, either by increasing the activity of infected T cells prior to their death and/or by activation of dendritic cells, which are known hosts for HIV. Consistent with this are the findings that HIV transcripts have been identified in the skin of patients with HIV-associated psoriasis and within both CD4+ T cells and dendritic cells (46).

Known as the Koebner phenomenon or the isomorphic response, induction of psoriasis at sites of trauma is a well-known reaction seen in about 25% of psoriasis patients (47). This is an all-or-none type of a response, such that if psoriasis occurs at one site of injury, it will occur at all sites. It is typically seen in patients with active disease or during periods of flare, and manifests around 7–14 days after the injury.

Several other factors have been implicated in the onset of psoriasis. One prominent factor is stress, particularly acute stressful events (48). Patients with high stress have

been found to have more severe disease (48b), which is perhaps not surprising as psoriasis can be emotionally disabling, particularly in those severely afflicted (48d). Psoriasis typically develops or flares from 2 days up to a month after the initial stressful event (16).

Finally, smoking (49) and several drugs have been implicated in triggering flares of psoriasis; these include medications such as antimalarials, beta-blockers, lithium, nonsteroidal anti-inflammatory drugs, imiquimod (16), and, curiously, anti-TNF (tumor necrosis factor) agents, which are highly effective against psoriasis (50). The majority of patients who experience flares following anti-TNF treatment have worsening or new onset of chronic plaque psoriasis, but around 40% present with pustular flares of the palmar and plantar surfaces, often in association with chronic plaque psoriasis elsewhere on their skin (50b). The pathologic mechanisms underlying these flares could involve cross-regulation of interferon alpha (IFN- $\alpha$ ) and TNF (51). The non-uniformity of this phenomenon also suggests an element of heterogeneity in the inflammatory network in psoriasis.

## 150.6 COMORBIDITIES

Psoriasis, particularly severe disease, has been shown to be associated with an increased risk of myocardial infarction (52) and death (53). Psoriasis patients also have increased prevalence of the metabolic syndrome (54), being more likely to have diabetes, hyperlipidemia and higher body-mass index (48c,55), with severe psoriasis being more likely in obese individuals (49). Interestingly, the increased risk of myocardial infarction persists even after adjusting for all these covariates (52), as has been observed in other systemic inflammatory diseases (56). These observations suggest that a state of systemic inflammation, perhaps promoted by shared genetic susceptibility variants, may predispose to atherosclerosis in these disorders.

## 150.7 HISTOPATHOLOGY AND LESIONAL EVOLUTION

Psoriasis is characterized by markedly increased epidermal growth and altered differentiation in association with immunological, inflammatory, biochemical, and vascular abnormalities, along with a poorly understood relationship to nervous system function (16). Fully developed psoriatic lesions are characterized by uniform elongation of the rete ridges of the epidermis with thinning of the epidermis overlying the dermal papillae (Figure 150-3). There is altered differentiation in the epidermis with confluent parakeratosis (retention of nuclei) in the stratum corneum and accompanied loss of the granular layer. Nearly all basal keratinocytes are proliferating in psoriatic skin compared to less than 10 percent in normal skin (57), and this is accompanied by a large increase in the metabolic activity of epidermal cells (58). Dilated, tortuous capillaries appear in the dermal papillae with a markedly increased number of lymphocytes, macrophages, dendritic cells and mast cells. Neutrophils tend to collect within the epidermis, either in the stratum corneum where they form microabscesses (of Munroe) or smaller collections in the spinous layer (spongiform pustule of Kogoj).

The transition from uninvolved skin to fully developed psoriasis proceeds through several stages. It is of interest that normal-appearing skin of patients with psoriasis manifests subtle morphologic and biochemical changes involving lipid biosynthesis (58a,59) and innate immunity (60). The earliest changes noted in a developing lesion are marked edema and infiltration of mononuclear cells (61). The overlying epidermis begins to demonstrate edema between the keratinocytes (spongiosis) and there is focal loss of the overlying granular layer. Accompanying these changes is dilatation of the superficial blood vessels. In developing lesions there is gradual increase in the thickness of the epidermis accompanied

**FIGURE 150-3** Histopathology of psoriasis. Comparison of uninvolved (left) versus involved (right) skin from the same individual. Psoriatic lesions are characterized by marked increased thickness of the epidermis with prolongation of the rete pegs, altered differentiation with loss of the granular layer, and overlying confluent parakeratosis in the stratum corneum. There is dilatation and increase tortuosity of dermal blood vessels in the dermal papillae and mononuclear infiltrate that is composed of macrophages, dendritic cells, and T cells.

with increased metabolic activity and DNA synthesis (58a,62). There is an increased number of T cells and dendritic cells in the dermis (63) along with increased number of degranulated mast cells and dermal macrophages (58a,62). In the center of the lesions, rete ridges begin to elongate with more confluent parakeratosis eventuating into a fully developed psoriatic plaque.

## 150.8 IMMUNOPATHOGENESIS

Multiple lines of evidence suggest that psoriasis is a T-cell mediated disease, driven at least in part by a positive feedback loop from activated T cells to antigen-presenting cells, with contributions from innate immune mechanisms involving the epidermis, macrophages (64), vascular epithelium, and possibly mast cells (65). Psoriasis was for many years thought to be mediated by T helper 1 cell (Th1) IFN- $\gamma$ -secreting cells (66), but recently the focus has shifted toward a novel subset of CD4+ T lymphocytes producing interleukin 17 (IL-17) (67) and/or IL-22 (65), and therefore named Th17 and Th22 respectively. These cells are increased in psoriatic lesions (65,67) and while their differentiation from naïve CD4+ T cells is induced by the cytokines IL-1 and IL-6 (68,69), their maintenance and expansion is dependent on IL-23 (70), which is derived from dendritic cells, macrophages, and keratinocytes, the latter likely at a lower level (71). Th17 cells are characterized by expression of the IL-23 receptor and produce and release the cytokines TNF- $\alpha$ , IL-17, IL-21, and IL-22, which sometimes is attributed to a separate Th22 subset (72). The importance of these cells in the pathogenesis of psoriasis is supported by the rapid decrease in Th17 responses seen with effective anti-TNF treatment (73). There is considerable plasticity in this system and Th17 cells have been shown to be able to change into IFN- $\gamma$ -producing Th1 cells (74). Given the increased number of both Th1 and Th17 cells in psoriasis (70), it is notable that the Th1-derived cytokine IFN- $\gamma$  programs myeloid-derived dendritic cells to induce Th17 cells via IL-1 and IL-23 (70). In psoriatic skin there is a distinct compartmentalization of T cells, with CD4+ T cells predominating in the upper dermis while CD8+ T cells mostly localize to the epidermis (75). Importantly, entry of T cells into the epidermis appears to be a crucial event in the development of psoriatic lesions (76). CD8+ T cells have a functional division similar to CD4+ T cells, with the majority producing TNF- $\alpha$  along with IFN- $\gamma$  (Tc1), IL-17 (Tc17), and/or IL-22 (Tc22), all of which are found in increased numbers in the psoriatic epidermis (65,77). These subsets have similar cytokine requirements as the T helper cells, with the Tc17 being similarly dependent on IL-23 for maintenance and expansion (78). Some CD8+ T cells in psoriasis are clonally expanded (79), suggesting that they may be responding to a limited set of antigens in the context of HLA class I molecules, notably HLA-Cw6. Although CD8+ T cells are thought to be primarily cytotoxic in nature, the injury might be

sublethal as psoriatic keratinocytes are relatively resistant to apoptotic damage (80). Thus, instead of causing cytotoxic death, these cells may promote the hyperplastic and pro-inflammatory psoriatic epidermal response through the release of cytokines (65). The CD8+ T cells are likely to be primed and activated through a process called cross-presentation (81). Cross-presentation involves the update of intracellular proteins from other cells by antigen-presenting dendritic cells, which in turn present them in the context of HLA class I on their surface (81). Cross-presentation is dependent upon CD4+ T-cell support (82), which might explain the observed dependence in psoriasis on CD4+ T cells in a xenograft mouse model (83). Keratinocytes contribute to the inflammatory response by producing effectors of innate defense known to be highly overexpressed in psoriasis, including the defensins hBD-2 and hBD-3, CCL20, CXCL9 and CXCL10, S100A7, S100A8, S100A9, and S100A15 (6,70,84). In addition to antimicrobial properties, many of these proteins have chemotactic activities, such as CCL20 for Th17 cells (85), and CXCL9 and CXCL10 for Th1 cells (86), which can amplify the inflammatory cascade. Other examples include induction of Th17 cytokines by the closely related S100A7 and S100A15 proteins (87) and beta-defensin 2, which increases production of IFN- $\gamma$  and TNF- $\alpha$  in T cells (88).

In addition to T cells and keratinocytes, other cell types play important roles in the inflammatory network in psoriasis. Macrophages are important cells of the innate immune system and are capable of antigen presentation and activating T cells during stimulation of the adaptive arm of the immune system (89), particularly after IFN- $\gamma$  priming as is observed with these cells in psoriasis (89). Macrophages are increased in psoriatic skin (89) and are located just under the basement membrane, adjacent to proliferating keratinocytes (90). These cells co-express inducible nitric oxide synthase (iNOS) and contribute to the inflammatory network in psoriasis through production and release of TNF- $\alpha$  and IL-23 (89). Based on findings in psoriasis-like mouse models, it has been suggested that macrophages may play a key role in the pathogenesis of psoriasis, at least in part through their TNF- $\alpha$  production (91).

Dendritic cells (DCs) may also play major role in psoriasis. Two main types of DCs are present in psoriatic lesions: plasmacytoid DCs and myeloid-derived DCs (92). Plasmacytoid dendritic cells are a specialized subset of DCs that are increased in number in psoriatic lesions and characterized by the ability to make IFN- $\alpha$  (93). Intravenous administration of IFN- $\alpha$  has been shown to worsen psoriasis in some patients (94). Similar exacerbations have been observed with the use of imiquimod, which acts through toll-like receptor (TLR) 7 located within plasmacytoid dendritic cells (95). IFN- $\alpha$  has multiple different actions including inducing cross-presentation of antigens and cross-priming of CD8+ T cells (96). IFN- $\alpha$  also induces the expression of major

histocompatibility complex (MHC) class I molecules on the surface of nucleated cells and can promote dendritic cell maturation (97). In a xenograft mouse model, it was shown that plasmacytoid dendritic cells initiate psoriasis through the production of IFN- $\alpha$  (98). A major factor in the activation of the plasmacytoid dendritic cells is thought to be a complex between DNA and the antimicrobial peptide cathelicidin, which is overexpressed in psoriasis lesions (99,100). However, the role of IFN- $\alpha$  in stable chronic plaque psoriasis has been questioned, based on the results of a clinical trial of a neutralizing anti-IFN- $\alpha$  monoclonal antibody (mAb) (101). Myeloid DCs include epidermal Langerhans cells and inflammatory dendritic epidermal cells (IDECs), as well as resident and inflammatory dermal DCs (92,102). In psoriatic lesions there is a marked increase in the number of inflammatory DCs expressing iNOS and/or key inflammatory cytokines such as TNF- $\alpha$  and IL-23 that in turn induce generation and expansion of Th17 T cells and activation of the keratinocytes (70,92).

Beyond the several cellular players described above, mast cells, neutrophils, and endothelial cells have all been suggested to play a role in the inflammatory network. Mast cells are increased in developing psoriatic lesions (58a) and have prominent degranulation in active lesions (58b). In addition to large numbers of inflammatory mediators, mast cells have been shown to be able to produce both IFN- $\gamma$  (103) and IL-17 (65). Neutrophils are commonly seen in the upper epidermis of the psoriatic lesions, where they may accumulate in small aggregates (spongiform pustule of Kogoj) or microabscesses in the stratum corneum (Munro microabscesses) and can be a source of IL-17 (65). The relevance of IL-17 production by mast cells and neutrophils in comparison to the production and release from activated T lymphocytes (65) is still unclear. Suggestive of an important role for mast cells, c-kit mutant  $W^{sash}/W^{sash}$  mice, which are nearly devoid of mast cells (104), display markedly defective early inflammatory and immune responses in the imiquimod-treated mouse model of psoriasiform inflammation (105). Endothelial cells are also likely to be active participants in the pathogenic process. Endothelial cells are strongly activated in developing and mature psoriatic lesions (58a,106) and play a major role in controlling the influx of inflammatory cells and serum proteins into psoriatic lesions.

### 150.9 PSORIASIS SUSCEPTIBILITY LOCI AND THEIR ROLES IN DISEASE PATHOGENESIS

Motivated by the favorable genetic epidemiology of psoriasis described earlier, several groups embarked on a search for genetic determinants of psoriasis in the 1990s (107). These studies relied on the property of genetic linkage (i.e. either consistent co-segregation of a particular genetic marker with disease, or sharing of alleles in

affected sibling pairs). However, except for the *PSORS1* locus, these studies yielded no consistent evidence for linkage to specific non-MHC loci (reviewed in (108)). The same problem has been encountered in a variety of other complex genetic disorders (109), mainly due to the high population frequency and low penetrance of disease alleles in many complex genetic disorders (110). In this setting, tests of association are much more powerful than tests of linkage, provided causal variants or proxies for them can be genotyped (111). However, in contrast to linkage studies, population-based association studies comparing allele frequencies in cases and controls require at least 100,000 genetic markers to comprehensively survey the genome (112). Thus, genome-wide association studies (GWAS) were not feasible in the 1990s, and genetic association studies were limited to candidate genes or regions. Since then, however, millions of genetic markers have become available in the form of single nucleotide polymorphisms (SNPs) (113). Concurrently, technologies were developed for high-throughput genotyping, allowing 100,000–1,000,000 SNPs to be typed in thousands of individuals at a reasonable cost. These developments have led to major advances in the genetics of psoriasis as well as many other complex genetic disorders (114). While there are large remaining gaps in our ability to account for all of the heritability known to exist in such disorders (115), these studies have provided major insights into the genetic architecture of many common yet complex diseases.

Because of the large number of markers being tested, GWAS require fairly stringent criteria for declaring statistical significance, as well as having a requirement for independent replication (116). Using a fairly generous significance criterion of  $p < 5 \times 10^{-7}$ , 25 psoriasis susceptibility loci have been reported at genome-wide levels of significance as of this writing. Using the more stringent criterion of  $p < 5 \times 10^{-8}$ , this number declines to 21 (Table 150-1). While in most cases the true causal variants responsible for these association signals remain to be identified, it is intriguing that many of these loci map close to genes that broadly map into a few distinctive biological pathways. Most of these are immunologic in nature and have to do with antigen processing and presentation, the Th1/Th17 inflammatory axes, and TNF- $\alpha$  and nuclear factor kappa B (NF- $\kappa$ B) signaling, as well as dendritic cell and macrophage activation. However, additional loci appear to be pertinent to epidermal barrier function and innate immune defense. Below, we will discuss these loci in the context of their hypothesized roles in psoriasis pathogenesis (Figure 150-4). While we group these genes into several axes, we would emphasize that these axes interact in many important ways.

#### 150.9.1 Antigen Presentation

It has been known for almost four decades that a major risk gene for psoriasis is located within the major

TABLE 150-1 Psoriasis Susceptibility Loci

Chromosome	Nearby Gene or Locus	OR (95% CI)	Risk Allele	Cases	Controls	P-Value	Association Reported with Other Inflammatory Phenotypes	Reference
1p31	<i>IL23R</i>	1.49 (1.27–1.74)	T	0.35	0.29	$3 \times 10^{-08}$	Cr, UC, AS, PBC, BD	(126a)

Loci yielding  $p < 5 \times 10^{-8}$  in at least one study, and two loci (*IL28RA* and *GJB2*) closely approximating this threshold, are shown. AS = ankylosing spondylitis; BD = Bechet's disease; CD = celiac disease; Cr = Crohn's disease; HIES = hyper-IgE syndrome; KID = keratitis ichthyosis deafness syndrome; MS = multiple sclerosis; PBC = primary biliary cirrhosis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SS = Sjogren syndrome; T1D = type 1 diabetes; UC = ulcerative colitis.

histocompatibility complex (MHC) region on chromosome 6 (117), and more recently that it resides in the class I end of the MHC (118). With the advent of GWAS to provide an unbiased view of the entire genome, the pre-eminence of the MHC's genetic influence has become clear in psoriasis, as it has in other complex immune/inflammatory disorders, including systemic lupus erythematosus, rheumatoid arthritis, and multiple sclerosis (119). However, for all of these disorders, the genetic dissection of the MHC has proven to be quite a challenge. The MHC is characterized by strong linkage disequilibrium (LD), as first reported as early as 1968 (120). Early studies suggested that LD extended more than 2 Mb in some cases, but not all (121). This differs from the LD pattern reported for other regions in the genome, where strong LD exists in segments averaging approximately 22 kb (122). However, closer inspection reveals that the local structure of LD in the MHC is similar to

that found across the rest of the genome, except that a higher amount of long-range LD is observed between shorter segments of more typical LD, resulting in extended or ancestral haplotypes (121,123). Although the psoriasis MHC risk variant had been mapped to the vicinity of human leukocyte antigen (HLA)-C through case-control association and family studies (118,124) this extensive linkage disequilibrium along with the high number of immune response genes in this region caused a great difficulty in identifying the true risk gene in this region, which was not achieved until 2006 (125). In that study, through the use of recombinant ancestral haplotypes along with DNA sequencing of critical intervals, HLA-Cw\*0602 was identified as the most likely disease allele in this region (125). However, it was recently shown, using logistic regression analyses adjusting for HLA-Cw\*0602 status, that there are at least two additional loci within the MHC region. One of them

**FIGURE 150-4** Integrating the genetics and immunology of psoriasis. Genes identified as psoriasis-associated are italicized in boxes. Upper mid panel—Most of CD4+ T cells are localized in the dermis (purple), whereas CD8+ T cells are predominantly localized in the epidermis (green). Around 5% of CD8+ T cells in the epidermis and CD4+ T cells in the dermis produce IL-17 (yellow halo). Macrophages (MΦ), plasmacytoid dendritic cells (pDCs), and myeloid dendritic cells (DC) all participate in the inflammatory network of psoriasis. Psoriatic epidermis is hyperproliferative, characterized by increased number of mitoses and marked elongation of the rete ridges. The *LCE3B* and *LCE3C* deletion is thought to be involved in epidermal repair, whereas the role of *SERPINB8* in the epidermis is not fully known. Left upper panel—IFN-γ is able to prime DCs to increase production of IL-23, which in turn can signal through the IL-23 receptor on T cells to increase production of IL-17. IL-17 acts primarily on the epidermis, with increased production of pro-inflammatory cytokines and antimicrobial peptides such as beta-defensins, which are highly expressed in psoriatic lesions. Another source of IL-17 can be mast cells (purple). Several genes involved in this inflammatory axis have been identified as psoriasis-susceptibility genes. IL-13 may influence Th1/Th17 polarization or may have other immunomodulatory effects on this inflammatory axis. Right upper panel—Antigen presentation now appears to be central to the pathogenesis of psoriasis. Several genes involved in antigen processing and presentation have now been identified as risk factors. Right middle panel—NF-κB pathway regulation is central to many inflammatory processes. The NF-κB pathway is downstream of multiple cytokines, such as TNF-α, as well as pattern-recognition receptors such as toll-like receptors. Several genes involved in modulating and regulating NF-κB signaling seem to have a major role in psoriasis. Left lower panel—*NOS2*, which encodes for inducible nitric oxide synthase, is primarily located in DCs and MΦ in psoriatic lesions. It is strongly induced by IFN-γ and can amplify immune responses through generation of oxidized phospholipids. Right lower panel—pDCs may have a central role in pathogenesis of psoriasis and are the major source of type I and type III interferons. Two genes involved in this pathway were recently identified as risk genes in psoriasis. (Modified with permission from Nair et al. (197).)

is located within an intron of the open reading frame *C6orf10* and the second one is located between HLA-B and the *MICA* gene (126). The function of *C6orf10* is not known, but *MICA* is a distant homolog of the MHC class I proteins and can be induced by cellular stress in epithelia and interact with T cells (126b).

The class I human leukocyte antigens are expressed on the surface of all cells and have a critical role in host defenses against intracellular pathogens through the presentation of peptide antigens (typically but not always of intracellular origin) to CD8+ T cells (127) (Figure 150-4). Consistent with a role for HLA-Cw\*0602 in the

pathogenesis of psoriasis, CD8+ T cells are the predominant cell type in the epidermis of psoriatic lesions (75). Some of these cells are clonally expanded (79), and their entry into the epidermis is essential for the triggering of disease in a mouse xenograft model (76). HLA-C can also serve as a ligand for killer immunoglobulin-like receptors (KIRs), which can either inhibit or stimulate natural killer (NK) cells (6). The *KIR* locus has been associated with psoriatic arthritis (128) and would be a plausible candidate in the pathogenesis of psoriasis. However, our current understanding of HLA-C-KIR interaction involves a dimorphic allotype of HLA-C (Asn80/Lys80).

*HLA-Cw6* is one of several “group 2” alleles carrying Lys 80. Thus, if this mechanism were responsible for the observed association of *HLA-Cw6* with psoriasis, it would be expected that a combination of all “group 2” alleles would provide a stronger association signal in individuals carrying the cognate inhibitory KIR genotype than does *HLA-Cw6*, but this was not the case for psoriatic arthritis (125). Thus, the role of *HLA-Cw6* as a genetic regulator of NK cell activity in psoriasis remains to be clarified.

A recent genome-wide association study provided further evidence for the autoimmune basis of psoriasis through the identification of a gene involved in antigen recognition by T cells. This gene, *ZAP70*, which encodes for a tyrosine kinase that is involved in CD8+ T-cell responses, was recently recognized as a likely risk gene for psoriasis, but only in those who also carry *HLA-Cw6* (129) (Figure 150-4). This kinase is closely associated with the T-cell receptor and has a major role in setting the response threshold of the T cell, which is critical for avoidance of autoreactivity (129).

Psoriasis has also been associated with the *ERAP1* gene, which encodes an endoplasmic reticulum aminopeptidase that is involved in the trimming of peptides for presentation by MHC class I molecules (129,130). Interestingly, this association is only associated with disease in *HLA-Cw6+* individuals, further highlighting the likely functional importance of MHC class I antigen presentation in general, and of *HLA-Cw6* in particular (129). Another recently identified susceptibility locus contains *PSMA6*, a proteasomal subunit involved in MHC class I antigen processing that is overexpressed in psoriatic lesions (131) (Figure 150-4). However, this region also contains *NFKB1A*, which is an attractive candidate gene for psoriasis because it encodes I $\kappa$ B $\alpha$ , a major inhibitor of NF- $\kappa$ B signaling (129,131).

### 150.9.2 The IL-12/IFN- $\gamma$ and IL-23/IL-17 Axes

T lymphocytes have been shown to have a major role in psoriasis pathogenesis, best exemplified by the remarkable clinical efficacy of cyclosporin A (132). The most prominent subsets of T cells are of the Th1 and Th17 lineages, and although it was initially thought that these two axes had inhibitory effects on each other (133), it has recently been shown that under some circumstances, such as those that exist in psoriatic lesions, there is synergistic interaction (70) and plasticity between the two, as Th17 cells have been shown to be able to change into IFN- $\gamma$ -producing Th1 cells (74), although not vice versa. Th1 cells are the main source of IFN- $\gamma$ , whereas Th17 cells are characterized by expression of the IL-23 receptor and produce and release the cytokines TNF- $\alpha$ , IL-17, IL-21, and IL-22, which in some circumstances appears to be attributable to a separate Th22 subset (72). Other cells may contribute to this, such as mast cells, which, as

described earlier, have been demonstrated to be a source of both IL-17 and IFN- $\gamma$  in psoriasis (65,103); neutrophils; and macrophages, which may contribute to local IL-22 production (65). Through the production of these cytokines, they have profound effects on the epidermis, with activation of keratinocytes and elicitation of other pro-inflammatory cytokines, growth factors, and antimicrobial peptides (134).

Genetic studies have demonstrated that polymorphisms close to or within several of the genes involved in these immunological pathways increase the risk of psoriasis. Thus, polymorphisms in the *IL12B* gene (126a,135), which encodes the p40 subunit that is shared by IL-12 and IL-23; the *IL23A* gene (126a), encoding the p19 subunit of IL-23; and *IL23R* (135), encoding the unique subunit of the IL-23 receptor, have all been shown to increase the risk of psoriasis (Figure 150-4). When considered alongside recently published functional studies implicating IL-23 in the spontaneous development of psoriasis lesions in a xenograft model (136) and the remarkable clinical efficacy of anti-p40 treatment in psoriasis (137), these genetic associations strongly reinforce the biological significance of the Th1 and Th17 inflammatory axes in the pathogenesis of psoriasis. The clinical overlap between psoriasis and other chronic inflammatory diseases such as ankylosing spondylitis and Crohn's disease may be explained, at least in part, by shared risk alleles such as in the *IL23R* gene (138). Other loci close to or within genes involved in these pathways have recently been published. Thus, polymorphisms in the *TRAF3IP2* gene, which encodes CIKS/ACT1, have been shown to increase risk of psoriasis (139). ACT1 is a signaling adapter for IL-17-mediated cellular responses (139b), binding to the cytoplasmic tail of the IL-17 receptor (140) and linking it, through TNF-receptor-associated factors (TRAF) 3 and TRAF6, to downstream signaling of the MAPK and NF- $\kappa$ B pathways (140,141). Perhaps surprisingly, the psoriasis-associated polymorphism resulted in a near complete loss of ability of ACT1 to interact with TRAF6 (139b). TYK2 is a member of the Janus family of kinases (142), was recently implicated as a susceptibility gene in psoriasis (129) and encodes for a protein tyrosine kinase that has a central role in the signaling of multiple cytokines including IL-12 and IL-23, thus affecting both generation of Th1 and Th17 cells (142), and IFN signaling (129).

### 150.9.3 TNF- $\alpha$ and NF- $\kappa$ B Signaling

The transcription factor nuclear factor kappa B (NF- $\kappa$ B) is ubiquitously expressed, is a key player in regulation of both innate and adaptive immune responses (143), and has a major role in regulation of epidermal differentiation and proliferation (144). Given the central importance of this signaling pathway, it is tightly controlled with a large number of positive and negative regulators. Dysregulation of this pathway, as was demonstrated in mice with epidermis-specific deletion of *Ikk2*, which

leads to inhibition of NF- $\kappa$ B activation, results in severe inflammatory skin disease (145). Interestingly, the transgenic mice were indistinguishable from their littermates at birth but developed the inflammatory phenotype spontaneously after few days and this phenotype was TNF- $\alpha$ -dependent (145). NF- $\kappa$ B also plays a major role in the immune cell infiltrate in psoriasis, perhaps most prominently in macrophages (146). Macrophages (89), along with dendritic cells (147), are a significant source of TNF- $\alpha$ , which expression is dependent on the activation of NF- $\kappa$ B signaling, and TNF- $\alpha$  in turn is a potent activator of NF- $\kappa$ B itself (148a,b,c). This suggests that NF- $\kappa$ B signaling is necessary for normal epidermal homeostasis and that dysregulation of this system can lead to skin inflammation that is dependent on TNF- $\alpha$ , which may be primarily derived from the inflammatory infiltrate.

Several loci involved in this pathway have been implicated as susceptibility genes for psoriasis (Figure 150-4). *TNIP1* and *TNFAIP3* (126a) encode for the A20 and ABIN1 proteins, respectively. These proteins interact with each other, and may act at multiple steps in the NF- $\kappa$ B signaling pathway (149), with a net result of pathway inhibition (150). In most cell types, baseline A20 expression is very low, but its transcription is rapidly induced upon NF- $\kappa$ B activation. A20 is also able to inhibit TNF-induced NF- $\kappa$ B activity (151) and may also interact with other signaling molecules such as TRAF6 (152), which is downstream of the IL-17 receptor (149). Polymorphisms near *TNFAIP3* yield genome-wide significant associations with rheumatoid arthritis (153), Crohn's disease (138a), and systemic lupus erythematosus (154). As these polymorphisms are not the same or in linkage disequilibrium with those associated with psoriasis, it suggests that different alleles of *TNFAIP3* can lead to different chronic inflammatory diseases (6). It is of interest that susceptibility to atherosclerosis maps to the *Tnfaip3* locus in mice (155), particularly as atherosclerosis is a major comorbidity of psoriasis (52), systemic lupus erythematosus (156), and rheumatoid arthritis (b). *REL* (129) encodes c-Rel, one of the five principal members of the NF- $\kappa$ B family of transcription factors. It has been implicated in the development of Foxp3+ regulatory T cells (157) and is also expressed in the epidermis, where it has a role in epidermal development and homeostasis (158). The *NFKB1A* (129,131) locus has also been shown to increase risk of psoriasis, and the product of this gene, I $\kappa$ B $\alpha$ , is one of three proteins that associate with NF- $\kappa$ B dimers in their inactive state in the cytoplasm (159). I $\kappa$ B $\alpha$  is a part of a negative feedback loop where nuclear NF- $\kappa$ B drives I $\kappa$ B $\alpha$  expression that in turn inhibits NF- $\kappa$ B activation (159). In the absence of I $\kappa$ B $\alpha$ , the termination of NF- $\kappa$ B activation in response to stimuli such as TNF- $\alpha$  is significantly delayed (145,160). *FBXL19* (131) is another psoriasis-susceptibility candidate that has been proposed to have a role in NF- $\kappa$ B signaling (131). FBXL19 is structurally related to FBXL11, an F-box family member shown to inhibit

NF- $\kappa$ B (131). However, its exact role in regulating this signaling pathway is presently unknown.

#### 150.9.4 Dendritic Cell/Macrophage Function

Two of the major sources of key cytokines in psoriasis, including IL-1, IL-12, IL-23, and TNF- $\alpha$ , are macrophages and dendritic cells (89,147), which are found in increased numbers in psoriatic lesions in spatial proximity with both CD4 and CD8 T cells (63a,161). As described earlier, a subset of inflammatory dendritic cells, often referred to as TIP-DC, are thought to play a key role in the pathogenesis of psoriasis (147). This is supported by the rapid down-modulation of their products, including TNF- $\alpha$  and IL-23, with effective treatment of psoriasis (73). A prominent feature of TIP-DC is the expression of the inducible isoform of nitric oxide synthase (iNOS) (89,147), which when expressed rapidly liberates large amounts of nitric oxide (NO). A variant in the *NOS2* gene locus, which encodes iNOS, was recently shown to increase risk of psoriasis (131). Nitric oxide plays a vital role in the regulation of inflammation (162). IFN- $\gamma$  is a very potent inducer of iNOS and in addition to producing NO, iNOS can also be a source of superoxide, hydrogen peroxide, and peroxynitrite (163). These free radical species react rapidly with proteins and lipids in their vicinity, generating oxidized phospholipids that in turn can activate macrophages, with a resulting increase in pro-inflammatory cytokine production (Figure 150-4). Interestingly, besides IFN- $\gamma$  signaling, iNOS is also regulated through NF- $\kappa$ B pathway activation (143).

#### 150.9.5 The Epidermal Barrier and Antimicrobial Defenses

The epidermal barrier itself may play a role in psoriasis susceptibility (Figure 150-4) as deletion of two genes, *LCE3C* and *LCE3B*, encoding two structural epidermal proteins, increases the risk of psoriasis (164,165). The expression of these genes is low-to-undetectable in normal skin (164) but they are highly expressed in lesional skin in those patients that do not carry the deletion (164). Interestingly, there is an epistatic interaction between the *LCE3C* and *LCE3B* deletion and the *HLA-Cw6* locus, although this appears to differ between populations (165,166). Although the mechanism behind the increased susceptibility with this deletion is still unclear, it has been suggested that these two proteins are involved in barrier repair after epidermal injury or inflammation (167), although this incompletely addresses the epistasis with the HLA-C locus. Other recently implicated loci in psoriasis include one harboring the connexin 26 (*GJB2*) and serine protease inhibitor B8 (*SERPINC8*) genes (129,130). Connexins form a part of gap junctions, but these are highly specialized membrane structures that form channels between the cytoplasm of adjacent

cells, providing a means for the exchange of ions, second messengers, and small metabolites (168). At least nine connexin genes are expressed in skin and these play a crucial role in keratinocyte growth and differentiation (168). Mutations in the connexin 26 gene are associated with several distinct skin disorders, most of which are characterized by markedly thickened epidermis, often on the palms and soles, in association with sensorineural deafness (168,169). Interestingly, connexin 26 has been shown to be upregulated in psoriatic epidermis (170) and persistent expression of connexin 26 in a transgenic mouse model led to epidermal barrier defects and development of a psoriasis-like phenotype with increased proliferation of keratinocytes and immune infiltration (171). Serine protease inhibitors (serpins) are a large superfamily of structurally related proteins that regulate the activity of proteases involved in diverse biological processes. Little is known about the exact biological function of serpin protease inhibitor B8, but its localization in the epidermis has been described (172). Finally, the number of copies an individual carries of a gene cluster encoding three epidermally expressed antimicrobial peptides (human beta-defensins 2, 3, and 4), has been shown to influence psoriasis risk, with a higher number of copies conferring a higher risk (173). This interesting finding still requires independent confirmation.

### 150.9.6 Other Genetic Risk Factors

Several other genes have been implicated as susceptibility genes for psoriasis. These include variants close to or within the *IL4/IL13* gene cluster on chromosome 5 (126a). IL-4 and IL-13 are Th2-related cytokines that influence immune responses, and abnormalities in this system may polarize the immune response away from Th2 toward Th1- or Th17-mediated responses (70). The polymorphism associated with psoriasis is non-synonymous, resulting in amino acid change of the IL-13 cytokine. Interestingly, the A allele of IL-13 (R130Q) is associated with asthma and atopy (174), whereas the G allele is associated with psoriasis (126a). The asthma-associated R130Q variant has been shown to signal more effectively through the IL-13R $\alpha$ 1/IL-4R $\alpha$  heterodimeric receptor, as measured by STAT6 phosphorylation, and binds less well to the inhibitory IL-13R $\alpha$ 2 receptor (175). Thus, the psoriasis-associated variant may have an opposite effect with greater signaling through the IL-13R $\alpha$ 2 receptor and decreased affinity for the IL-13R $\alpha$ 1/IL-4R $\alpha$  heterodimeric receptor. This is of interest as IL-13 has been shown to be able to induce production of TGF $\beta$ 1 through the IL-13R $\alpha$ 2 receptor on macrophages (176), and overexpression of TGF $\beta$ 1 in a transgenic mouse model has been shown to result in a psoriasis-like skin disorder (177). Several loci located close to genes involved in interferon signaling were recently implicated in psoriasis (129). These include the interleukin 28 receptor, alpha (*IL28RA*), and the interferon-induced helicase

C domain-containing protein 1 (*IFIH1*) (129), which also has been implicated as a risk factor for type 1 diabetes (178). Currently, not much is known about the function of these candidate genes in psoriasis. In addition, a putative regulatory variant within the *ZNF313-RNF114* gene has been associated with psoriasis in two independent genome-wide association studies (131,179). *ZNF313* belongs to a family of E3 ubiquitin ligases (179). E3 ligases have been associated with the pathogenesis of several autoimmune conditions (180) but the role of this variant in psoriasis is unknown.

A GWAS performed in Han Chinese clearly implicated *HLA-Cw\*0602*, *IL12B*, and the *LCE3B/LCE3C* indel associations (165), and a subsequent follow-up study implicated *ERAP1* and confirmed the *TNIP1* association described earlier. An additional set of loci, including *PTTG1*, *CSMD1*, and *ZNF816A* in addition to the *GJB2* and *SERPINB8* genes described above (127), has thus far been identified only in Chinese populations, possibly due to allelic heterogeneity.

Taken together, the identification of these susceptibility loci has dramatically changed our view of the pathogenic mechanisms operating in psoriasis. Instead of looking at psoriasis as a purely T-cell mediated disease, it is now evident that defects in multiple different cellular compartments play a role in its pathogenesis (Figure 150-4). The identification of *HLA-Cw6* as one of the major susceptibility genes, the interaction with *ERAP1*, and the association with *ZAP70*, strongly implicates HLA class I antigen presentation to CD8+ T cells as a central element in psoriasis pathogenesis. In addition, *IL12B*, *IL23A*, *IL23R*, and *TYK2* are likely to have a major role in amplifying the Th17 response in psoriasis, and *TRAF3IP2* is likely to regulate intracellular signaling downstream from the IL-17 receptor. The NF- $\kappa$ B regulatory variants may play active roles downstream of cytokines such as TNF- $\alpha$  and IL-17. As endorsed by *IFIH1*, interferon signaling also appears to be central in causing or triggering the disease. The *IL4/IL13* locus may influence the Th2 vs Th1/Th17 balance, either via IL-4 (181), or via IL13 (182). The importance of the epidermal compartment is suggested by the fact that several susceptibility loci harbor genes thought to be involved in epidermal barrier formation, repair, and defenses. All of these findings are consistent with the hypothesis that psoriasis is maintained by a T-cell response against a limited set of self-antigens, likely due to an underlying defect in immunologic tolerance maintained by cross-presenting macrophages and dendritic cells (81), and amplified by type I interferons such as IFN- $\alpha$  (183).

### 150.10 MANAGEMENT

There is a broad range of both topical and systemic agents available for the treatment of psoriasis. Mild to moderate disease is typically treated with topical agents, often along with ultraviolet phototherapy. As topical

treatments are often cosmetically unacceptable and time-consuming to apply, non-compliance is high (184). When choosing a treatment regimen for patients with psoriasis, several different factors need to be taken into account. The extent and the measurable severity of the disease needs to be considered along with the patient's own perception of his or her disease. As psoriasis is a chronic disease it is important to consider the long-term safety of the treatment along with patient's comorbidities, which may increase their risk of toxicity. Finally, treatment efficacy may diminish with time, a well-known phenomenon in psoriasis, termed tachyphylaxis.

The most common topical therapy used is topical steroids. Improvement is usually achieved within 2–4 weeks, with maintenance treatment consisting of intermittent applications. Long-term treatment may lead to thinning of the skin (atrophy), telangiectasia and prominent stretch marks (striae). Other topical agents used include vitamin D3 analogs (185), retinoids, topical calcineurin inhibitors, dithranol, and coal tar (186). Phototherapy is a very effective way to control mild to moderate psoriasis and often works synergistically with topical agents. The mechanism of action of phototherapy appears to involve selective depletion of T cells, predominantly those that reside in the epidermis (40,187). Several systemic oral agents are available for treatment of psoriasis and are usually reserved for patients with more severe disease. Methotrexate is highly effective for chronic plaque psoriasis (188) and is also used for management of other subtypes of psoriasis such as erythrodermic and pustular psoriasis (189). It is also very effective in the treatment of psoriatic arthritis (190). Although methotrexate inhibits dihydrofolate reductase, it is its activity on AICAR transformylase, an enzyme involved in purine metabolism, that is thought to be the main mechanism of its anti-inflammatory activity (191). This leads to accumulation of extracellular adenosine, which has potent anti-inflammatory activities (191). Acitretin is a systemic retinoid that is used for psoriasis although its mechanism of action is not fully understood, and is particularly effective for generalized pustular and erythrodermic psoriasis (189). Cyclosporine A is another T-cell immunosuppressant that was in common use prior to the advent of biologics and is very effective in the treatment of severe psoriasis, although side-effects limit it to short-term use. Other oral systemic agents available but not commonly used include sulfasalazine, fumaric acid esters, and mycophenolate mofetil (189).

The treatment of severe psoriasis has changed dramatically in the past decade, with the introduction of biologic agents. Currently, three anti-TNF agents are available for use in psoriasis—infliximab, etanercept, and adalimumab. Given the central role of TNF- $\alpha$  in psoriasis, as described before, it is perhaps not surprising that these agents are highly effective in treating both psoriasis and psoriatic arthritis and may also reduce the risk of cardiovascular events in patients

with chronic inflammatory disorders (192). Recently, a new biologic, ustekinumab, was approved for the treatment of psoriasis. This medication binds the p40 subunit of IL-12 and IL-23 and prevents interaction of these cytokines with their receptors (193). As described earlier, this treatment blocks IL-12, which is central to the development of Th1 cells and is inhibitory for Th17 (71,194) and Th22 (195) cells through its neutralizing effect on IL-23. Thus, it affects a biologic pathway that maps many of the susceptibility loci in psoriasis, including *IL12B*, *IL23A*, *IL23R*, *TRAF3IP2*, and *TYK2*. Clinical studies have demonstrated that this treatment is highly effective in psoriasis and has slightly greater effect than etanercept (196). A large number of systemic agents are currently in development for the treatment of psoriasis, several of which block pathways previously identified from genetics, and it is foreseeable that the next few years are going to be very exciting in terms of our understanding of the central disease processes in psoriasis as well as our ability to target them therapeutically.

## 150.11 CONCLUSION

With the recent successes in mapping out susceptibility loci and genes, we now have the beginnings of a genetic blueprint that can help point us toward molecular pathways that are central to the pathogenic process. Although it is foreseeable that this blueprint is going to become even more comprehensive with the elucidation of additional causative variants, we are now finally able to begin to understand how such a distinctive pattern of cutaneous inflammation develops in this fascinating yet enigmatic disease.

### Biographies

**Johann E Gudjonsson, MD, PhD**, is an assistant professor at the Department of Dermatology at the University of Michigan. Dr Gudjonsson graduated from the University of Iceland Medical School, receiving his medical degree in 1998 and a PhD in immunology and genetics in 2003. He has been the recipient of several awards and honors, including the Young Investigator Award of the American Academy of Dermatology in 2007, and the Frances and Kenneth Eisenberg Emerging Scholar of the A. Alfred Taubman Medical Research Institute in 2010. He is the director of Inpatient and Consultation Dermatology at the University of Michigan Health System, and has been listed on the Best Doctors in America since 2010.

Dr Gudjonsson's research is focused on the genetic basis of psoriasis and his work has contributed to the isolation of several risk genes. The main focus of his work is on how specific risk alleles influence inflammatory pathways, and creating tools to determine how combinations of different risk genes influence inflammatory processes in the skin, and effectively map out these processes.

**James T Elder, MD, PhD**, was named in 2008 as the Kirk D. Wuepper Professor of Molecular Genetic Dermatology. Dr Elder received MD and PhD degrees in molecular biophysics and biochemistry from Yale University. After a molecular biology postdoctoral fellowship at the University of California (Berkeley), he completed an internship in internal medicine and a dermatology residency and fellowship at the University of Washington, followed by a senior research fellowship at the University of Michigan. Board-certified in dermatology.

Dr Elder directs an active research laboratory at the University of Michigan in addition to his clinical duties. Dr Elder's laboratory utilizes tools of molecular biology and genetics to better understand several human skin diseases. The lab is a world leader in the use of genetic linkage and association techniques to learn more about how the immune system activates the epidermal wound healing mechanism in psoriasis, and triggers joint destruction in psoriatic arthritis. In 2006, his laboratory identified HLA-Cw6 as the disease allele at *PSORS1*, the major psoriasis-susceptibility locus in the major histocompatibility complex (MHC). His current efforts in this area are focused on identification of psoriasis susceptibility genes outside the MHC, with 20 loci confirmed thus far. His laboratory is also carrying out a combined analysis of global gene expression and DNA variation in psoriasis, as well as a genome-wide scan for psoriatic arthritis genes.

## Cutaneous Hamartoneoplastic Disorders

*Katherine L Nathanson*

Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

### 151.1 INTRODUCTION

Cutaneous hamartoneoplastic disorders encompass a wide variety of syndromes, among which are neurofibromatosis types 1 (NF1) and 2 (NF2), schwannomatosis, tuberous sclerosis complex (TSC), nevoid basal cell carcinoma syndrome (NBCCS) or Gorlin syndrome, PTEN hamartomatous syndrome (encompassing Cowden disease and Bannayan–Riley–Ruvalcaba syndrome), hereditary leiomyomatosis and renal-cell cancer (HLRCC), and Birt–Hogg–Dubé syndrome (BHD) (Table 151-1). These syndromes are linked as each is associated with susceptibility to tumors and has characteristic dermatologic features, in some cases neoplastic and in some non-neoplastic. All of these syndromes are addressed in detail in other chapters, except HLRCC and BHD, which are covered in detail below.

### 151.2 HEREDITARY LEIOMYOMATOSIS AND RENAL-CELL CANCER

#### 151.2.1 Genetics of HLRCC

Hereditary leiomyomatosis and renal-cell cancer (HLRCC; Online Mendelian Inheritance in Man (OMIM) 150,800) is a syndrome characterized by the development of cutaneous and uterine leiomyomas and renal cancer. Multiple cutaneous and uterine leiomyomas (MCUL) was initially described in 1973 by Reed et al. as an autosomal dominant syndrome (1). In 2001, two families were reported with renal cancer as well as multiple cutaneous and uterine leiomyomas by Aaltonen et al. and termed HLRCC (2). In their report, they speculated that this syndrome is a variant of that described earlier. They also noted the aggressiveness and the distinct histology of the renal cancers in patients with HLRCC (3). The region containing the gene was mapped using linkage to 1q42–44. The gene in which mutations were responsible for HLRCC was identified quickly as fumarate hydratase (*FH*) by an international consortium (4).

Individuals with a single mutation in *FH* develop HLRCC; those with biallelic mutations (homozygous or compound heterozygotes) develop fumarate hydratase deficiency (FHD). FHD is a rare metabolic disease in which patients develop fumaric aciduria, progressive encephalopathy, hypotonia, failure to thrive, and seizures (5–12). Patients with FHD usually do not survive beyond the first few months of life, although some more mildly affected individuals have been described (11,12). Relatives of these patients have been reported to develop cutaneous and uterine leiomyomas, and as such are at risk to develop renal cancer (4,11).

Over 300 families have been described with HLRCC (13–15). The percentage of patients and families that have personal or familial medical histories (e.g. multiple cutaneous leiomyomas or type two papillary renal cancer) identified with mutations in *FH* has varied substantially depending on the study. In the initial reports, encompassing 56 HLRCC families seen at the US National Cancer Institute (NCI), 52 (93%) were found to have mutations in *FH* (16,17). Expanding the phenotype, the percentage has decreased, as in the French National Cancer Institute “Inherited predisposition to kidney cancer” network’s study, which found mutations only in 71% (40/56) (13). However, there has not been the suggestion that additional predisposition genes exist for HLRCC. The group based at the NCI found mutations scattered across the gene, whereas the Multiple Leiomyoma Consortium initially reported clustering of mutations in the 5′ region of the gene, but that has changed with the identification of additional families (4). All types of point mutations have been reported, with missense mutations by far the most predominant (57%; 191/337) in the *FH* mutation database ([http://chromium.liacs.nl/lovd\\_sdh/home.php?select\\_db=FH](http://chromium.liacs.nl/lovd_sdh/home.php?select_db=FH)) (15). Large genomic deletions have been described but are rare (4,16,18,19). There have been some recurrent mutations reported in *FH*, including c.905-1G>A in families of Jewish Iranian background; p.R58P, which has been seen in several families; and nucleotide 698 appears to be

TABLE 151-1 Cutaneous Hamartoneoplastic Disorders

Syndrome	Gene	Protein	Neoplastic Dermatologic Disease	Non-Neoplastic Dermatologic Findings	Associated Cancer Types
Birt–Hogg–Dubé syndrome	<i>FLCN</i>	Folliculin	–	Fibrofolliculomas	Renal cancer—oncocytic, chromophobe

CML = chronic myelogenous leukemia; MDS = myelodysplastic syndromes.

a mutational hotspot leading to p.R233H and p.R233C (4,18,20). Missense mutations have been postulated to have a dominant negative effect. As FH exists as heterotetramer, only one in 16 subunits would be composed entirely of wild-type protein if one allele encoded an altered protein. This paradigm would be similar to that seen in other classic genetic syndromes, such as collagen disorders. However, recent studies have demonstrated similar reductions of FH activity in patients with both missense and truncating mutations, decreased by at least 50%, suggesting that the dominant negative hypothesis is not correct in vivo (13). The lower fumarate hydratase enzymatic activity in affected patients has been proposed as a method for screening of family members, however genetic testing remains a more efficient method to detect affected individuals (21).

No genotype–phenotype correlations have been reported in multiple studies; in fact, intrafamilial heterogeneity has been observed in multiple cases, despite similar decreases in FH activity (13). The penetrance for the complete phenotypic manifestations of HLRCC has yet to be fully defined, although similarly to many cancer susceptibility syndromes, as more families are

tested, individuals with mutations but no manifestations of disease have been identified. This finding has led to the consideration of modifiers of penetrance, and as such a family-based study was done to attempt to identify other linked genes, but did not identify a modifier (22). However, this study was limited in design and lower, and modifiers of penetrance, either genetic or environmental, may exist.

Mutation screening has been suggested for all sporadic cases of papillary type II renal cancer with the appropriate histologic subtype, particularly in the setting of a positive family history and early-onset disease (23). Several studies have looked at patients with isolated papillary type II, identifying mutations in 17%; however, pathologic screening should be done to select patients (13). A series of patients with early-onset uterine leiomyosarcoma (diagnosed under the age of 45) were screened, and only 1/67 (1.5%) found to have mutations; genetic testing for *FH* mutations would not be cost-efficient in that population (24). However, mutation testing also needs to be considered in families with multiple women with aggressive uterine leiomyomas (25).

### 151.2.2 Fumarate Hydratase Biology

The fumarate hydratase gene, *FH*, spans 22kb, with ten exons, and encodes two fumarate isoenzymes, cytosolic and mitochondrial. FH catalyzes the conversion of fumarate to malate in the tricarboxylic acid (TCA) cycle. Consistent with a postulated role as a tumor suppressor gene, loss of the wild-type allele is observed in cutaneous and uterine leiomyomas, as well as renal cancer, from individuals with *FH* mutations (2–4,18,26). The active form of FH is a homotetramer, in which three of the four chains combine to form the enzymatic active site (27). Loss of FH results in accumulation of fumarate and other TCA intermediates. Along with mutations in the succinate dehydrogenase complex (SDH), leading to susceptibility to pheochromocytoma and paraganglioma, and *VHL*, leading to von Hippel–Lindau disease, mutations in *FH* have been long thought to lead to a “pseudohypoxic” state.

Hypoxia sensing is primarily mediated through the hypoxia-inducible factors (HIFs), which are transcription factors that regulate adaptation to tissue hypoxia. HIF is a heterodimer that is composed of an unstable  $\alpha$ -subunit (e.g. HIF1 $\alpha$ ) and a stable  $\beta$ -subunit (e.g. HIF1 $\beta$ /ARNT). There are three known HIF $\alpha$  genes, with the best characterized being *HIF1 $\alpha$*  and *HIF2 $\alpha$* . HIF1 $\alpha$  and HIF2 $\alpha$  have shared and independent target genes. HIF1 $\alpha$  activates genes associated with glycolysis and BNip3, while HIF2 $\alpha$  activates cyclin D1, vascular endothelial growth factor (VEGF), transforming growth factor alpha (TGF $\alpha$ ), and Oct4 (28–31). Under normoxic conditions, VHL binds to the hydroxyproline residue on the HIF- $\alpha$  subunits, targeting them for ubiquitination and proteosomal degradation (32). The generation of the hydroxyproline is catalyzed by the prolyl hydroxylase domain-containing proteins (PHDs), a subclass of 2-oxoglutarate (2OG) oxygenases, which use O<sub>2</sub> and 2-ketoglutarate ( $\alpha$ -KG) as substrates. PHD2 is inhibited under hypoxic conditions, allowing transcription of HIFs (33,34). Dysregulation of HIF has long been known to be important in the development of von Hippel–Lindau-associated tumors. Mutations in SDH-associated tumors also have linked to stabilization of HIF1 $\alpha$ , in a study demonstrating that elevated levels of succinate inhibit its prolyl hydroxylation by the PHDs (35). Upregulation of Hif1 $\alpha$  and its target genes has also been shown many times, including in mouse embryonic fibroblasts from Fh1-deficient mice (36); accumulation of fumarate also inhibits the PHDs, even more potently than succinate (37). Both fumarate and succinate act as competitive inhibitors of PHDs, although the mechanism of action may differ between the two TCA cycle intermediates (38,39). With the loss of FH, and thus TCA cycle function, several studies have explored energy production in these cells. FH-deficient tumors take up large amounts of glucose and shift to aerobic glycolysis (40,41). They maintain partial TCA cycle function through the uptake of glutamine, and dispose

of excess carbon through the synthesis of heme, and its excretion from the cell as bilirubin (42). Gottlieb et al. demonstrated that the inhibition of heme oxygenation was synthetically lethal with FH loss, suggesting it could be a potential therapeutic target (42).

Despite the role that excess fumarate plays in creating a “pseudohypoxic” environment through HIF stabilization, how it leads to tumor formation has not been well defined. A recent study using back crosses in mice has shown that neither the presence of *Hif* nor the absence of *Phds* is required for renal cyst formation in an Fh1-deficient background; in fact, loss of *Hif1 $\alpha$*  exacerbates renal cystic development (43). Two recent studies have demonstrated that FH loss results in activation of Nrf2-dependent activation of antioxidant pathways (43,44). NRF2, a transcription factor, is a key regulator of the antioxidant response, with multiple target genes that contain NRF2 response elements (45). Cellular levels of NRF2 are regulated by KEAP1 (Kelch-like ECH-associated protein 1), which is the substrate recognition subunit of a Cul3-based E3 ubiquitin ligase. Through tandem mass spectrometry, Ooi et al. and Adam et al. showed that fumarate modifies critical cysteine residues (Cys155 and Cys288) within KEAP1, so that it is unable to bind to NRF2 and target it for degradation (43,44). Upregulation of NRF2 may be an alternative pathway, other than through “pseudohypoxia,” which may lead to FH-deficiency-associated tumorigenesis, although the exact mechanism remains to be elucidated.

### 151.2.3 HLRCC Disease Manifestations

**151.2.3.1 Renal Cancer.** The predominant pathologic type of renal cancer associated with HLRCC is papillary type II; however, other types of renal cancers are observed, including collecting duct and clear-cell cancers (16,18,46). Independent of underlying architecture, cells in the renal cancers associated with HLRCC have a characteristic pathologic appearance, with large nuclei with inclusion-like orangeophilic or eosinophilic nucleoli surrounded by a clear halo (47).

As many of the mutations leading to HLRCC in *FH* are missense, leading to stable but inactive protein, immunohistochemistry for FH is not a reliable marker to detect those renal papillary type II tumors associated with HLRCC. Fumarate reacts spontaneously with cysteine sulfhydryl groups to chemically modify proteins, in a process termed succination. Recently, immunohistochemistry for S-(2-succinyl) cysteine (2SC) has been proposed as a marker of FH loss, and thus mutations in *FH* (48). Pollard et al. validated it as an immunohistochemistry marker on over 1000 specimens, correctly predicting the presence of *FH* mutations (48,49). Thus, use of immunochemistry to identify patients who need evaluation for HLRCC and subsequent genetic testing for mutations in *FH* may become part of clinical practice. In particular, this methodology may be helpful, as standard

immunohistochemistry markers have not identified a characteristic pattern of staining (47). Array-based comparative genomic hybridization (aCGH) has been done to characterize FH-deficient renal cancers. Loss of chromosome 1q was found, as expected, consistent with the tumor suppressor role of *FH*, as were gains of chromosomes 2, 7, and 17, and losses of 13q12.3021.1, 14, 18, and X, suggesting a distinct genetic profile for these renal tumors (50). However, specific genetic associations have not yet been identified.

Overall, approximately 20% of families with HLRCC have renal cancer, usually a single proband (15,51). However, there is significant variability in the reported prevalence of renal cancer in families and patients with HLRCC, depending on how the proband was ascertained. In the series from NCI, 62% of families with MCUL/HLRCC had an individual with renal cancer; most probands were ascertained through a hereditary renal cancer program (16). In studies ascertaining on the basis of multiple cutaneous leiomyomas, the frequency of renal cancer is low, at 1–2% and 16% in two series (17,18). The standardized incidence ratio (SIR) has been calculated at 6.5 for renal cancer in HLRCC, comparing Finnish families with *FH* mutations with the general population (230-fold in the 15–29-year-old age group, and 45-fold in the 30–44 age group) (26).

Renal cancers associated with HLRCC tend to be early onset, high grade and aggressive. Patients can also have predominantly cystic lesions, as well as the more common solid tumors (26). The incidence of renal cysts has been reported to be as high as 36% in patients with HLRCC, and they are observed in *Fh1*-deficient mice (26,52). Metastatic renal cancer in individuals as young as 17 has been reported, with the youngest age of onset reported as 11 years (53,54). The average age of diagnosis is approximately 40 years, substantially younger than sporadic renal cancer (46). In general, renal cancer in HLRCC is solitary, however there have been a few reports of bilateral and multifocal disease (46,47). In one series of 40 renal tumors, all of the tumors were characterized as high grade (Fuhrman grade III or IV) based on the aberrant nuclei (47). In the initial study describing HLRCC, all six patients with renal cancer presented with metastases and died of their disease (2). While the absolute numbers have decreased in more recent studies, a similar pattern has been seen, with 10 of 19 (53%) patients either dead or with advanced disease with a median follow-up of 34 months (46). Many reports of malignant disease exist, and most patients die within 5 years after diagnosis (51). Thus, the natural history of renal cancer in HLRCC is different than for other hereditary renal cancer syndromes, which tend to exhibit multifocal disease with a relatively benign natural history, leading to differences in screening guidelines, reviewed below.

**151.2.3.2 Uterine Leiomyomas.** Uterine leiomyomas (fibroids) are benign tumors that arise from the smooth

muscle cells of the uterus. They are extremely common; in the United States, by the age of 50, they are found in the 70% of white women and over 80% of women of African ancestry (55). They also are the most frequent non-renal manifestation of HLRCC, and develop in 75–98% of female patients (2,4,16). The leiomyomas tend to be early onset and severe, diagnosed on average 10 years earlier than in sporadic disease, with 68% diagnosed before the age of 30 in one series (16,56). The histopathology of the uterine leiomyomas associated with HLRCC appears to be quite similar to that of the renal tumors, in particular the nuclear features, with prominent eosinophilic nucleoli surrounded by a clear halo (57). Comparing women with *FH* mutations with those without mutations in the same family, the risk was statistically significantly increased, with an odds ratio of 7.6 (95% confidence interval (CI) 2.9, 20) (56). Most women have surgical treatment of their leiomyomas, with many having hysterectomies before the age of 30 (56). The early age of hysterectomy in women with HLRCC may have an adverse impact on their ability to bear children, however that has not been universally reported (16,56). Uterine leiomyosarcomas have been observed in the European population and in Finland; the SIR was calculated at 71 (26). Leiomyosarcomas have not been reported in the North American population, potentially as hysterectomy is more frequent. However, recent studies suggest that the risk of uterine leiomyosarcoma was overestimated, as when the uterine tumors in the Finnish families were re-reviewed according to the latest World Health Organization (WHO) criteria, they were classified as benign mitotically active or atypical leiomyomas; additionally, no tumor necrosis was seen, which is an essential component of leiomyosarcomas (51). Thus, only one true malignant uterine leiomyosarcoma has been reported. As such, the risk of sarcomatous transformation is low in patients with HLRCC.

**151.2.3.3 Cutaneous Leiomyomas.** Cutaneous leiomyomas (piloleiomyomas) are painful pink-purplish nodules that affect individuals in a disseminated or segmental distribution. They are benign tumors that arise from the piloerector apparatus (17). Cutaneous leiomyomas occur in 80–100% of individuals with HLRCC, with a mean age of presentation of 25 years (range 10–47 years), but can develop later into the 40s (58). In a study from The Netherlands, all patients with HLRCC over the age of 40 had cutaneous leiomyomas (14). The appearance and symptoms associated with the cutaneous disease can vary widely. They are usually 5–20 mm in diameter, and can range from flesh-colored to pink or brown (58). Patients have a variable number of lesions, from 1 to 100, usually on the extremities and trunk, rarely on the face. They can be clustered or widely scattered all over the body. Mild presentations are seen in 40%, with five or fewer lesions (14,16–18). However, some patients have very severe symptomatic presentations, associated with pain, usually in response to temperature change and touch. There have

been two case reports of skin leiomyosarcoma in association with *FH* mutations (16,17).

**151.2.3.4 Other Tumor Manifestations.** Wilm's tumor has been reported in two pediatric patients with *FH* mutations, suggesting a possible associated predisposition (14,59). Leydig-cell tumors have also been reported in a patient with HLRCC. Screening of sporadic Leydig-cell tumors also identified a second male with a germline mutation, suggesting that patients with Leydig-cell tumors should be asked about pertinent family history (60). Gastrointestinal stromal tumors (GIST), adrenocortical disease, and ovarian cystadenomas have also been described in patients with HLRCC (61–63).

### 151.2.4 Medical and Surgical Management of HLRCC

The greatly increased risk of early onset aggressive renal cancer in HLRCC necessitates screening and quick intervention. While there are no standard guidelines for renal cancer screening, patients have been diagnosed as young as 11 years; however, it is the only report of a patient below the age of 15 (53). Thus, screening should start at age 15, with abdominal/pelvic computed tomography (CT) or magnetic resonance imaging (MRI) annually. Given the aggressive nature of these lesions, radical nephrectomy at diagnosis (regardless of tumor size) is the recommended treatment strategy as soon as lesions are identified. Cutaneous and uterine leiomyomas are much more common than renal cancer in HLRCC. The cutaneous leiomyomas can be quite painful and have cosmetic implications; they are treated with standard dermatologic methods. Women with uterine leiomyomas should be advised about the options in terms of uterine preservation and potential impact on child bearing. The leiomyomas themselves should be followed on an annual basis.

## 151.3 BIRT-HOGG-DUBÉ SYNDROME

### 151.3.1 Genetics of Birt-Hogg-Dubé Syndrome

Birt-Hogg-Dubé syndrome (BHD) is an autosomal dominant syndrome characterized by the development of fibrofolliculomas, renal cancer, predominantly hybrid oncocytic tumors, and lung cysts and pneumothorax. An inherited syndrome associated with fibrofolliculomas in two siblings, and a description of similar skin lesions in their father, along with intestinal polyps, was initially described by Hornstein and Knickenberg in 1975 (64). Subsequently, a large Canadian family was described by Birt, Hogg, and Dubé, three dermatologists, in which 15 of 70 family members had lesions they called fibrofolliculomas, abnormal dilated hair follicles with a hyperplastic mantle of connective tissue (65). This family also had trichodiscomas and acrochordons. Since the initial

description of these families, it has been recognized that they constitute one syndrome—Birt-Hogg-Dubé (BHD). Although renal cancer was not included in the initial descriptions of BHD, the association between renal cancer and BHD was subsequently noted, first in 1993 by Roth et al. (66). In 1999, Toro et al. enlarged upon the association, describing 7 of 13 patients with renal cancer (67). The gene for BHD was mapped to 17p12–17q11.2 using genome-wide linkage analysis by two groups in 2001 (68,69). Quickly thereafter, the gene in which mutations are associated with BHD was identified and named folliculin (*FLCN*) (70). The protein had no homology to previously identified proteins, but was found to be conserved across species and expressed in a wide spectrum of normal tissues, including skin, lung, and kidney.

Most mutations in *FLCN* are truncating, nonsense, and frameshift, although missense mutations and large genomic rearrangements have been described (71,72). Multiple groups have noted that mutations are most frequently found within a C<sub>8</sub> tract in exon 11, and are either insertions or deletions (73–75). Of note, when the two most common mutations, c.1285dupC and c.1285delC (previously 1733insC and 1733delC), were compared, the insertion was associated with a higher rate of renal cancers ( $p=0.03$ ) (73). An association of mutations in exon nine with lung cysts, and thus pneumothorax ( $p=0.0002$ ), has been suggested (76). Missense mutations and in-frame deletions in *FLCN* have been investigated for pathogenicity, and found to disrupt protein stability (77). The same study also found a highly conserved domain between amino acids 100 and 230, identified by computational analysis. There are two *FLCN* mutation databases (<http://grenada.lumc.nl/LOVD2/shared1>, <http://www.skingenetdatabase.com/home.php>), which can be used for reference for mutation characterization and single nucleotide polymorphism (SNP) identification; however, only the former is currently maintained (78,79).

Over multiple series of families with clinically defined mutations in BHD, mutations in *FLCN* are found in approximately 85% of families (73,76,80,81). Although some series have not included large genomic rearrangement testing, which may increase the percentage of patients with clinically defined BHD carrying *FLCN* mutations, a recent series from The Netherlands including such screening only identified 22/27 (81%) families with mutations (81). Of note, however, two of the remaining five families carry likely pathogenic *FLCN* exon one deletions, which if included would have increased the mutation detection rate to 88%. Most families described with BHD due to mutations in *FLCN* have the three classic manifestations of lung cysts, renal cancer, and fibrofolliculomas, although each individual may not have all three manifestations. However, mutations in *FLCN* also have been found in familial isolated spontaneous pneumothorax and patients with multiple lung cysts, without

other evidence of BHD (82–85). BHD is likely the most common cause of familial isolated pneumothorax (86). Rarely, familial isolated non-clear-cell renal cancer has also been associated with mutations in *FLCN* (87). Thus, phenotypically differing conditions are associated with *FLCN* mutations, so genetic testing may be indicated in the absence of classic BHD.

Criteria for the diagnosis of BHD have been proposed, and include major criteria of (1) at least five fibrofolliculomas, at least one histologically confirmed, of adult onset; or (2) pathogenic *FLCN* mutation. Minor criteria are (1) multiple lung cysts: bilateral basally located lung cysts with no other apparent cause, with or without spontaneous pneumothorax; (2) renal cancer: early onset (<50 years) or multifocal or bilateral renal cancer, or renal cancer of mixed chromophobe and oncocytic histology; and (3) a first-degree relative with BHD (88). Patients should have one major or two minor criteria for diagnosis. BHD is certainly vastly underdiagnosed. As BHD has become increasingly recognized by pulmonologists as a cause of lung cysts and pneumothorax, referrals to many cancer or medical genetics clinics, and thus diagnoses of BHD, have seen a significant rise in the past 5 years. Furthermore, BHD is not associated with a decrement in reproductive fitness, so many large families with multiple affected members have been observed.

### 151.3.2 *FLCN* Biology

*FLCN* was validated by several studies as a tumor suppressor gene lost in renal cancer associated with BHD. Unusually, the second allele of *FLCN* is most frequently inactivated by point mutation rather than loss (89). Somatic mutations in *FLCN* are infrequently identified in sporadic renal cancers (90,91). However, neither loss of heterozygosity nor *FLCN* mRNA expression is observed in fibrofolliculomas, so it is possible that haploinsufficiency is enough to allow their development (92,93).

Two animal models of BHD have occurred naturally, in the rat and dog (94,95). In the “Nihon” rat, which contains a point mutation in the rat homolog of *BHD*, homozygosity leads to early fetal demise, and heterozygosity is associated with early onset of renal cancers, predominantly clear cell (94). The syndrome of hereditary multifocal renal cystadenocarcinoma and nodular dermatofibrosis (RCND) was described in German shepherds prior to the identification of *FLCN* as the causative gene for BHD. The gene was mapped into a region syntenic to that also mapped for BHD, and a point mutation was found in the canine homolog of *FLCN* (95). Similarly to the rat model, homozygosity is embryonically lethal, and heterozygotes develop bilateral multifocal renal cystadenocarcinoma, uterine leiomyomas, and dysplastic hair follicles.

*FLCN* does not have homology to any other known protein and its function has been difficult to elucidate. Since heterozygous loss gives rise to such a diverse

spectrum of phenotypes, its function has not been clarified through an understanding of the disease process. Initially, several studies suggested that *FLCN* was part of the mTOR signaling pathway (96–99). Baba et al. linked loss of *FLCN* and upregulation of mTOR signaling as possibly mediated through an *FLCN*-interacting protein (FNIP1) and AMP-activated kinase (AMPK) (96,100). Studies in mouse models found downregulation of p-S6 with loss of *FLCN*, so the association between *FLCN* and mTOR signaling may be context dependent (101). Perhaps not surprisingly given the somewhat contradictory results, subsequent functional work has suggested that aberrant mTOR signaling may be associated with downstream effects, not directly with those mediated by *FLCN* (102). Two recent studies have implicated *FLCN* in TGF $\beta$  signaling (102,103). Profiling in UOK257, an *FLCN*-null renal cancer cell line derived from a BHD patient, in which wild-type *FLCN* was expressed, found differential expression of many genes involved in TGF $\beta$  signaling (103). Levels of TGF $\beta$ 2, INHBA, and SMAD7 were reduced in the *FLCN*-null line, and in BHD-associated renal tumors as compared with normal kidney. In *Bhd*<sup>-/-</sup> embryonic stem (ES) cells, resistance to apoptosis associated with decreased expression of Bim was observed, with the defects observed appearing similar to those seen in TGF $\beta$  receptor and ligand mutants (102). This observation was confirmed by showing that *Bhd*<sup>-/-</sup> ES cells have hypoacetylation of TGF $\beta$  target gene promoters. Although much further work needs to be done to fully elucidate the function of *FLCN*, these studies are the first steps to understanding the function of a protein that, when mutated, leads to a disparate set of phenotypes.

### 151.3.3 Disease Manifestations of BHD

The three major manifestations of BHD are fibrofolliculomas of the skin, renal tumors, and lung cysts/pneumothorax. As discussed above, most individuals with BHD do not have all three phenotypes, but within families all can be observed. Patients with *FLCN* mutations can be ascertained through dermatology (fibrofolliculomas), or pulmonary (lung cyst and pneumothorax) or urologic oncology (renal cancer). In each case, patients who present with isolated findings have been found to have *FLCN* mutations. Interestingly, a positive family history for renal cancer or pneumothorax is associated with a higher risk of those disease manifestations, but the converse is not true, in that a family history of renal cancer is not associated with an increase in risk of pneumothorax (71). This finding suggests that modifiers of BHD disease phenotype may exist, which may account for the variability in phenotype. In addition, the clustering of phenotypes within families may account for observed ascertainment biases; patients and families identified through dermatology clinics are likely to have lower rates of renal cancer than those seen in urologic clinics.

**151.3.3.1 Fibrofolliculomas.** Fibrofolliculomas of the skin appear in the 20s to 30s and are considered characteristic of BHD (74,93). Patients can have from only a few fibrofolliculomas on their cheeks to extensive involvement of the face, neck, and upper back in a “cape-like” pattern. Fibrofolliculomas are abnormal growths of the hair follicles with epithelial strands extending into the surrounding stroma. Generally, they are lighter than skin color, but can be skin-colored or slightly erythematous, and are dome shaped. In BHD, oral papules have also been described in up to 43% of patients, mostly localized on the lips and commissural folds, also arising after the age of 30 (67,104). Prior to the identification of *FLCN*, a clinical diagnosis of BHD was made based on having 10 lesions consistent with fibrofolliculomas, at least one biopsy-positive (80). In addition to fibrofolliculomas, acrochordons and trichodiscomas have been reported in some studies of BHD patients (65,74). However, other studies suggest that these lesions are incorrectly diagnosed fibrofolliculomas (105–107). Interestingly, loss of the second allele of *FLCN* is not observed in fibrofolliculomas and as such it is postulated that haploinsufficiency is sufficient for predisposition (93). The lesions do not cause any problems for patients beyond cosmetic. Successful treatment of the fibrofolliculomas with CO<sub>2</sub> laser treatment has been reported (108).

Confusion between angiofibromas and fibrofolliculomas has been reported, as they are both skin-colored papules and can be found across the cheeks. Angiofibromas are associated with the inherited diagnoses of tuberous sclerosis complex (TSC) and multiple endocrine neoplasia type 1 (MEN1). Angiofibromas tend to be flesh-colored or erythematous, and clustered in the nasolabial folds and across the cheeks and chin. In addition, patients with TSC can have forehead plaques and hypomelanotic macules on the face that extend around the neck and upper back. Familial multiple trichodiscomas (familial multiple discoid fibromas) has been described as a “look-alike” for Birt-Hogg-Dubé syndrome (74,109). The families are clinically distinct with early onset of skin lesions, involvement of the ear, both pinna and helix, and discoid fibromas without the follicular epithelial component characteristic of the fibrofolliculoma/trichodiscoma papules seen in BHD, and do not carry mutations in *FLCN* (109). The families do not have renal or pulmonary disease, as seen in BHD.

**151.3.3.2 Renal Cancer in BHD.** In a large series of patients studied with BHD, 20% (38/187) of individuals from 24 families, representing 45% of total families, had renal cancers (73). The number of renal cancers in each patient ranged from a solitary lesion to multifocal bilateral cancers. In this series of patients with BHD from the US National Institutes of Health (NIH), the renal cancer was male-predominant (27 males, 11 females) and the average age of diagnosis was 48 (range 31–71) (73). A follow-up series of 51 independent families found a higher rate, in that 34% of individuals and 49% of

families had renal cancer; 41% of families ascertained based on dermatologic findings (71). Many families have only a solitary individual with renal cancer (71). Other series of patients have observed slightly lower rates of renal cancer, consistent with the earlier reports, with lifetime risks (at age 70 years) of 16% (95% CI 6, 26%) (81). In the series with higher rates of renal cancer, the relative risk is estimated to be increased sevenfold (80). Several families described with multiple individuals with oncocytomas were found to have fibrofolliculomas and subsequently mutations in *FLCN*, suggesting that BHD accounts for familial oncocytoma in some cases (67,110).

A wide spectrum of renal cancers has been observed in patients with BHD, even within the same kidney. The most common type of tumor is an unusual hybrid oncocytic tumor (mixed oncocytoma and chromophobe). Observation of a hybrid oncocytic tumor in any patient should prompt an evaluation for BHD, as it is so characteristic of this disease. It has been suggested that oncocytomas and chromophobe tumors share a common cell of origin and have similar gene expression profiles (111,112). In a series of 84 tumors from 10 patients with BHD, 67% were hybrid oncocytic, 23% chromophobe, 7% clear-cell tumors, and 3% oncocytomas (113). Not only can multiple types of renal cancer be observed within a single kidney, within a BHD-associated renal cancer there can be multiple cell types. Small nodules of tumor similar to the large hybrid oncocytic tumors seen have been observed throughout the kidney, consistent with cancer-susceptibility syndrome with all cells predisposed to develop disease (114). While the malignant potential of the hybrid tumors has not been entirely elucidated, it appears to be low if present (112,113,115). The various studies have not noted features suggestive of metastatic behavior, such as the presence of distant metastases, vascular invasion, or tumor necrosis. Unfortunately, this benign behavior does not appear to be the case for the clear-cell renal cancers that arise in patients with BHD. As noted above, clear-cell renal cancer has been described in patients with BHD, along with the multiple other tumor types. The clear-cell tumors have been shown to have loss of 3p and/or mutations in *VHL* (114).

**151.3.3.3 Pulmonary Disease.** Lung cysts and pneumothorax are a major component of BHD and likely have the highest morbidity. They were initially described by Toro et al. in 1999 (67). A large series of 198 patients from 89 families were evaluated for lung cysts and pneumothorax (76). A total of 187 (89%) and 48 (24%) patients had lung cysts and pneumothorax, respectively. Not surprisingly, the presence of lung cysts ( $p=0.006$ ), number of cysts, cyst volume, and largest cyst volume and diameter (all  $p<0.0001$ ), were all related to risk of pneumothorax. The relative risk of pneumothorax has been estimated to be 50.3 (95% CI 6.4–352), decreasing to 32-fold when adjusted for other covariates (80). The pulmonary cysts in BHD are found predominantly in the lower medial zone of the lung, tend to be irregularly

shaped, can be multiseptated and located close to the pleura (116,117). When compared with the cysts seen in women with lymphangiomyomatosis, they are larger and less circular, as well as being found in a different distribution through the lungs (118). The pulmonary cysts are lined with epithelial cells, and include type II pneumocyte-like cells (119). Furuya et al. suggest that they may not be bullae or blebs, but hamartomatous cysts that grow slowly and rupture. Interestingly, they also stain positively for FLCN, suggesting that haploinsufficiency is enough to allow cyst formation (119).

**151.3.3.4 Other Manifestations.** Colorectal adenomas have been reported in association with BHD, as well as other cancers (74,120). However, it is not clear that any of these are found at rates higher than would be expected based on population-based incidence. Colonoscopy in 45 patients with BHD did not show an increased frequency of adenomas (80). Parotid oncocytomas have been reported as a manifestation of BHD, and FLCN has been found to be expressed in the acinar cells of the parotid (92,121). Larger studies, preferably prospective, will need to be done to evaluate the question of risk for other associated cancers.

### 151.3.4 Medical and Surgical Management of BHD

Patients do not necessarily have all of the three major manifestations of BHD; they can have any combination of findings. This feature of BHD is of particular importance to note when counseling family members of a proband with BHD. All family members need to have genetic testing for mutations in *FLCN*, whether or not they have evident manifestations of disease.

Currently, there are no standard-of-care consensus guidelines for screening for the manifestations of BHD in families with known disease. Both the risk of renal cancer and pneumothorax are of concern. Based on screening recommendations for other hereditary renal cancers, annual to biannual screening of the kidneys by MRI starting in the early 20s, given the earliest age of cancer diagnosis in patients with BHD, seems reasonable. Screening using ultrasound is too insensitive for small lesions (122) and annual CT may give too high cumulative radiation doses. Pavlovich et al. described the management of BHD-associated renal tumors in fourteen patients over a median follow-up of 38 months (113). Four patients with lesions less than 3 cm were observed without need for intervention and without evidence of distant metastasis. Of the ten patients with lesions larger than 3 cm, one patient underwent bilateral nephrectomy and renal transplant, unilateral nephrectomy with contralateral partial nephrectomy was performed in two patients, and seven underwent bilateral partial nephrectomy. Local recurrence in retained renal remnants was observed in three patients and two patients died from metastatic renal-cell cancer (RCC) (both of whom had

conventional RCC). The treatment of renal masses in patients with BHD follows a similar strategy as VHL: lesions smaller than 3 cm are observed and those larger than 3 cm undergo immediate surgical resection.

As the number and volume of lung cysts are associated with risk of pneumothorax, a baseline chest CT is helpful. Screening after the initial study depends on the initial findings, with those with multiple cysts needing regular (annual CT) scanning and pulmonary consultation. A lower threshold for pleurodesis may be warranted in patients with pneumothorax. Of importance, as patients are at increased risk of pneumothorax, they need increased intraoperative monitoring when having surgery. In addition, they should be advised against scuba or other deep-sea diving due to the risk of pneumothorax. In general, they are not advised against flying on commercial flights as cabins are pressurized. As smoking is a risk factor for both pneumothorax and renal cancer, patients are strongly encouraged not to smoke.

### Biography

**Katherine (Kate) L Nathanson** is Associate Professor of Medicine in the Division of Translational Medicine and Human Genetics, and the co-leader of the Abramson Cancer Center's Cancer Control Program. She trained in internal medicine and clinical genetics. Dr Nathanson is currently a physician–scientist who focuses on cancer genetics and genomics as a tool to improve to improve patient care. She maintains both an active clinical practice and laboratory research program. Her clinical practice focuses on inherited cancer susceptibility syndromes, predominantly focusing on those associated with hamartomatous syndromes, renal cancer, and endocrine tumors. In her research program, she investigates both the inherited and somatic genome in human cancers, specializing in testicular cancer, familial breast cancer, renal cancer, melanoma, and pheochromocytomas/paragangliomas.

## Inherited Disorders of the Hair

*Mazen Kurban*

Department of Dermatology, Columbia University, NY, USA

*Angela M Christiano*Department of Dermatology and Department of Genetics and Development,  
Columbia University, NY, USA**GLOSSARY**

**Acanthosis nigricans** – an ill-defined, velvety, hyperpigmented plaque involving the fold of the skin, including the axilla, neck and groin

**Atrichia** – absence of hair

**Atrophoderma** – atrophy of the skin

**Blepharitis** – inflammation of the eyelids

**Cicatricial alopecia** – scarring alopecia

**Copy number variations** – DNA segments with 1 kb or more of gains or losses

**Corneodesmosin** – a protein found in corneodesmosomes that is highly expressed in the upper layers of the epidermis, contributing to the skin membrane barrier. Moreover, corneodesmosin is highly expressed in the inner root sheath of the hair follicle

**Desmocollins** – specialized cadherin proteins that interact with themselves and with other proteins contributing to the formation of desmosomes

**Desmogleins** – specialized cadherin proteins that interact with themselves and with other proteins contributing to the formation of desmosomes

**Desmoplakins** – specialized proteins that connect the intermediate filaments to the desmosomal plaque, contributing to cellular integrity

**Desmosomes** – specialized intercellular structures that function in cell–cell adhesion

**Ectodermal dysplasia** – a group of disorders characterized by abnormal development of at least one of the following structures: hair, nails, sweat glands, and teeth

**Ectrodactyly** – also known as split hand foot. It is characterized by loss or defective central hand or foot digits, giving the appearance of lobster claws

**Forelock** – the area above the central part of the forehead

**Hemophagocytosis** – phagocytosis of blood components by histiocytes. It can occur in the bone marrow and other tissues

**Heterochromia** – a difference in color. Most commonly used to describe different iris colors

**Ichthyosis** – dry, thickened, scaly and flaky skin that resembles the skin of fish

**Ichthyosis linearis circumflexa** – migratory polycyclic and serpiginous erythematous plaques with double-edged scale at the margins, which are characteristic of Netherton syndrome

**Keratodermas** – disorders characterized by thickening of the skin of the palms and soles

**Keratosis follicularis** – in the text we used this term to describe erythematous papules arising in follicular regions; distinct from another genetic condition also known as keratosis follicularis, Darier's disease

**Milia** – white, keratin-filled papules that can appear on skin and mucous membranes

**Moniliform hair** – hair where several regular nodes are formed secondary to defects in the hair cortex

**Pachyderma** – thickening of the skin and particularly of the dermis resembling the thick skin of the elephant

**Pili torti** – twisted hair

**Plakoglobins** – belong to the family of armadillo proteins and are constituents of desmosomes and intermediate junctions

**Plakophilins** – belong to the family of armadillo proteins and are constituents of desmosomes

**Placode** – embryonic thickening of the epithelial layer from which the hair develops

**Steatocystomas** – epidermal cystic lesions that lack a granular layer and contain yellowish oily liquid and frequently hair structures and sweat glands

**Synophrys** – confluence of the eyebrows

**Trichomegaly** – excessive growth of the eyelashes

**Trichorrhexis invaginata** – also known as bamboo hair. A hair shaft anomaly due to intussusception of the hard keratinized part of the hair follicle into the softer non-keratinized portion

**Trichorrhexis nodosa** – weakening of the hair follicle leading to hair follicle splitting, giving the hair the appearance of a broom

**Trichoschisis** – a transverse break of the hair shaft at a region that is devoid of cuticle

**Vesicle** – a fluid-filled membrane-enclosed elevation in the skin

**Woolly hair** – is characterized by hair shaft anomalies that clinically present with tightly curled hair. Woolly hair is distinct from the tightly curly hair in African populations in that woolly hair shows hair shaft anomalies which can lead to hair loss and hair depigmentation

## 152.1 INTRODUCTION AND HAIR ANATOMY

The hair follicle (HF) is an important epidermal structure that plays a role in maintaining adequate internal body temperature control for several species during temperature extremes, and provides the first line of defense against environmental changes, toxins, and infectious agents. The hair is composed of several layers in cross section that work together in maintaining its integrity. The layers from the inside to the outside (Figure 152-1) are as follows. First is the hair shaft, which is made up of three layers: the medulla in the center is surrounded by the hair cortex and the hair shaft cuticle externally. The hair shaft is then surrounded by the inner root sheath (IRS), which itself is made up of three layers: the innermost part is referred to as the IRS cuticle, the middle part Huxley's layer, and the external part is Henle's layer. The IRS is then surrounded by a one-cell layer known as the companion layer, which separates the IRS from the next layer, the outer root sheath (ORS) of the HF. During

growth and differentiation of the several layers, keratin proteins are being expressed abundantly and differentially, providing a rigid structure for the HF (1). These keratins interact with the desmosomes formed between the cells, contributing to the integrity of the HF (2). Importantly, several mutations in keratins, desmosomes, and other proteins regulating their expression have been linked to several phenotypes in human hair disorders.

Longitudinally, the hair can be roughly separated into four regions (Figure 152-2): the bulb, which contains the matrix, the site where melanocytes reside, and which surrounds the dermal papilla (DP); the suprabulbar region, extending up to the site of arrector pili muscle insertion (the area of the bulge that contains the HF stem cells); the isthmus region, extending between the arrector pili muscle and the sebaceous gland; and the infundibular region that extends from the sebaceous gland to the skin surface. All the layers of the HF are derived from the hair matrix except for the ORS, which is contiguous with the basal interfollicular epidermis (1).

## 152.2 HF MORPHOGENESIS AND CYCLING

The formation of mammalian HFs occurs during embryogenesis through a series of reciprocal interactions between the ectoderm (epidermis) and the underlying

FIGURE 152-1 Structure of the hair follicle.

mesoderm (dermis) (3). The initial signal for hair development originates from the dermis, which signals to the overlying epithelium to form the placode. It is widely believed that the first signal is related to the Wnt signaling pathway (4). Wnt in the epidermis leads to abundance of  $\beta$ -catenin, which forms the placode (5). The placode then signals to the underlying mesoderm, forming the dermal condensate. Reciprocal signaling between the two compartments leads to the downgrowth of the placode (6,7). The placode then surrounds the dermal condensate, which will later on become the DP, and the cells in the placode proliferate and differentiate to make the several layers of the HF. Wnt/ $\beta$ -catenin expression is required for the activation of its direct transcriptional target, EDA receptor (EDAR), and therefore nuclear factor kappa B (NF- $\kappa$ B) signaling (8). EDAR functions in suppressing the placode inhibitory factors, mainly Dkk1, and thus indirectly potentiates the activity of the Wnt/ $\beta$ -catenin pathway (9).

Once the HF is formed, it begins to cycle. The hair cycle is divided largely into three phases (Figure 152-3), in addition to a recently described fourth phase, exogen (10). The growth phase, regression phase, rest, and shedding phases are termed anagen, catagen, telogen, and exogen, respectively. During cycling, the portion of the HF below the level of the isthmus goes through cyclic growth and regression, while the portion above the isthmus is permanent. The anagen phase is the longest phase, with variable duration depending on the body site. Generally, the anagen phase in the human scalp (longest hair anagen phase in humans) lasts 4–6 years. During the anagen phase, the lower part of the permanent HF (bulge) grows downward and forms the matrix of the HF, which differentiates into the various HF compartments (1). During the telogen phase, the club hair is encased by the

permanent portion of the HF, while during catagen the lower part of the HF undergoes apoptosis and regresses toward the permanent portion.

### 152.3 THE HAIR KERATINS AND THEIR REGULATION

The human genome has 54 functional annotated keratin genes, among which 28 belong to the type I keratin gene cluster and 26 belong to the type II gene cluster. All type II keratin genes cluster together on chromosome 12q13.13, while type I keratin genes cluster on chromosome 17q21.2, with the exception of keratin K18, a type I keratin, which is located in the type II keratin gene domain (11).

Among type I genes, 11 code for type I hair keratins, designated K31–K40 (previously known as Ha1–Ha8, Ka35, Ka36), while 17 code for type I epithelial keratins. Likewise, six of the type II genes encode hair keratins designated K81–K86 (previously known as Hb1–Hb6) while the remaining 20 code for epithelial keratins (12,13).

The main difference between hair and epithelial keratins is that hair keratins possess a greater amount of sulfur in their head and tail domains, which enables them to form tight cross-linking with keratin-associated proteins (KAPs) (14) that contribute to the hard structure of both hair and nails. Hair keratins are mainly expressed in the hair cortex and cuticle, and are structurally divided into three functional regions: the head domain, close to the N-terminus; the  $\alpha$ -helical rod domain, which includes the helix initiation and termination motifs; and the tail domain, which is close to the C-terminus. The rod domain is essential for the correct assembly with keratins of the opposite type, and therefore functional intermediate filaments. The head and tail domains are required for the interaction of the keratins with the KAPs (11).

FIGURE 152-2 The four longitudinal regions of the hair.

FIGURE 152-3 The hair cycle.

The differentiation of the hair and hair compartments involves the coordinated spatial and temporal expression of a large number of keratin genes. The production of the different keratins is a tightly regulated process that involves several transcription factors and proteins. FOXN1 plays a crucial role in the activation of genes involved in cortex and IRS differentiation. The most commonly affected keratins are keratin 33 and keratins 81, 85, and 86 (1). Moreover, downstream molecules of the Wnt signaling pathway trigger matrix cells toward cortex differentiation (6). HOXC13 is another transcription factor that is implicated in the regulation of hair keratins. The expression of HOXC13 overlaps with that of keratins 32, 35, 82, and 85. DLX3, a homeobox transcription factor, is another factor which regulates early signaling within the matrix, regulating the expression of hair keratin genes in the hair shaft and IRS (15). Several human hair phenotypes and syndromes with mutations in keratins or their regulatory proteins have been identified and will be discussed later in the chapter.

#### 152.4 DESMOSOMES OF THE HF

Desmosomes are intracellular adhesion structures that are critical for cell–cell attachment in the epithelial and myocardial tissues and in other tissues (16). The desmosomal cadherin family is a major structural unit of the

desmosome. It is composed of desmogleins (DSGs) and desmocollins (DSCs). DSGs and DSCs are glycoproteins containing a single transmembrane domain, through which they interact extracellularly, contributing to intercellular adhesion. Intracellularly, the cadherins bind to plakoglobins, plakophilins, and indirectly to desmoplakin, forming the desmosomal plaque. The desmosomal plaque interacts with the keratin intermediate filaments (KAFs). These interactions impart resilience and strength, and allow the distribution of physical impacts throughout tissues (17).

DSG(1–4) are all expressed in the human HF. *DSG4* is highly expressed in the precortex, keratinizing zone of the cortex, lower hair shaft cuticle, and the upper IRS cuticle (18). *DSG4* expression is regulated by several transcription factors, including HOXC13 and FOXN1 (2). Thus it is perhaps not surprising that mutations in any of these components would be associated with hair disorders.

#### 152.5 GENETICS OF HYPOTRICHOSIS AND OTHER STRUCTURAL HAIR ABNORMALITIES

Hypotrichosis denotes loss or reduction of HF density or integrity, and can affect any site on the body in both men and women. We and others have identified several genes associated with different types of hypotrichosis, where

**FIGURE 152-4** Generalized hereditary hypotrichosis simplex.

hypotrichosis occurs as an isolated finding or in the setting of a syndrome.

### 152.5.1 Disorders Involving the Wnt/ $\beta$ -Catenin Pathway

**152.5.1.1 Odonto-Onychodermal Dysplasia and Schopf–Schulz–Passarge Syndrome.** Odonto-onychodermal dysplasia (OODD; Online Mendelian Inheritance in Man (OMIM) 257980) is a rare autosomal recessive condition, described first in Lebanese families, and is characterized by hypotrichosis, onychodysplasia, palmar erythema and hyperhidrosis, palmoplantar keratoderma (PPK), oligodontia, and diffuse follicular hyperkeratosis. This condition is associated with deactivating mutations in the *WNT10A* gene, which produces an activator ligand of the Wnt/ $\beta$ -catenin signaling pathway (19). In addition to being crucial in hair morphogenesis, the Wnt/ $\beta$ -catenin pathway is also critical in the formation of other ectodermal structures. Not all patients with mutations in the *WNT10A* gene will present with hypotrichosis, perhaps due to the presence of several Wnt activator ligands that may compensate for its absence. Schopf–Schulz–Passarge syndrome (SSPS; OMIM 224750) is allelic to OODD, with mutations in the *WNT10* gene. SSPS has a similar presentation to OODD but a distinguishing feature is apocrine hidrocystomas (benign tumors of the sweat glands) that occur around the eyelids (20).

**152.5.1.2 Generalized Hereditary Hypotrichosis Simplex.** Hereditary hypotrichosis simplex (HSS; OMIM 605389) is an autosomal dominant condition characterized by a progressive hair loss involving the scalp, face, and body hair (Figure 152-4) (21). Patients

generally start to lose hair starting in the second half of the first decade, and progress to complete hair loss by the third decade of life. We have recently identified the gene mutated in this condition, *APCDD1*, in Pakistani and Italian families (22). We have demonstrated that *APCDD1* is a membrane-tethered protein abundantly expressed in the DP, the matrix, and the hair shaft of human HFs. Unlike WNT10, which functions as an activator of the Wnt/ $\beta$ -catenin pathway, *APCDD1* is an inhibitor of Wnt/ $\beta$ -catenin. Mutations in *APCDD1* are dominant negative against the wild-type allele. Therefore, we suggest that when *APCDD1* is mutated, Wnt/ $\beta$ -catenin is continuously activated, leading to depletion of HF stem cells. This may explain why people initially have normal hair and subsequently develop progressive hair loss.

### 152.5.2 Human Hair Disorders Involving the EDA-A1/EDAR/EDARADD Signaling Pathway

The EDA-A1/EDAR/EDARADD signaling pathway is part of tumor necrosis factor (TNF) superfamily pathway, and is crucial in hair morphogenesis since it functions to potentiate the activity of Wnt/ $\beta$ -catenin (see Section 152.2). Moreover, the TNF pathway is crucial for the development of other ectodermal structures, including teeth and sweat glands. EDA is a member of the TNF family and is a type II transmembrane protein that consists of three regions. In order to become functionally active, EDA must be cleaved and released out of cells, where it forms a trimer and binds to the EDAR (23). EDAR is a type I transmembrane protein and a member of the TNF receptor superfamily, with a

cysteine-rich domain in the extracellular region as well as a potential death domain in its intracellular region (18). Usually, EDA-A1 binds to EDAR and activates it, which then interacts with EDARADD through its death domain, resulting in the activation of NF- $\kappa$ B (24). Activation of NF- $\kappa$ B is essential for the development of the ectodermal structures and therefore mutations in genes along the TNF pathway lead to ectodermal dysplasia syndromes with overlapping clinical features, including sparse hair.

**152.5.2.1 Hypohidrotic Ectodermal Dysplasia.** Hypohidrotic ectodermal dysplasia (HED) is a disorder affecting the hair, teeth, and sweat glands. Clinically, patients show hypotrichosis and characteristic facies with a saddle nose, periorbital wrinkling with hyperpigmentation, conical teeth, and oligodontia (Figure 152-5), (see Chapter 148). Due to the impaired development of sweat glands, patients present with unexplained bouts of recurrent fevers. HED is most commonly inherited in an X-linked pattern (OMIM 305100) due to mutations in the EDA-A1 gene, although autosomal dominant (OMIM 129490) and autosomal recessive (OMIM 224900) inheritance due to mutations in the autosomal EDAR and EDARDD genes have been reported (18).

**152.5.2.2 X-linked Anhidrotic Ectodermal Dysplasia with Immunodeficiency and Incontinentia Pigmenti.** X-linked anhidrotic ectodermal dysplasia with immunodeficiency (XL-EDA-ID; OMIM 300291) is an X-linked recessive disorder that occurs mainly in males. This condition is caused by hypomorphic mutations in the *IKBKG* (inhibitory  $\kappa$ B kinase  $\gamma$  gene), which encodes NEMO (NF- $\kappa$ B essential modulator). The activity of NEMO is compromised, along with the TNF signaling pathway. Therefore, patients present with many features overlapping those of HED including the characteristic facies, atrichia or hypotrichosis, hypohidrosis,

oligodontia, and recurrent bouts of unexplained fevers. The main feature that distinguishes XL-EDA-ID from HED is the recurrent infections beginning early in life, since NF- $\kappa$ B is required for the maturation of the immune system (25). Incontinentia pigmenti (IP; OMIM 308300) is an X-linked dominant condition which is allelic to XL-EDA-ID. Unlike XL-EDA-ID, IP results from complete loss-of-function mutations in the NEMO gene and therefore this condition occurs almost exclusively in females because most males, except for those who are mosaic or are 47XXY, will die in utero (26). Clinically, patients present with perturbations in skin pigmentation with a variety of malformations affecting the skin, hair, teeth, eyes, heart, and central nervous system. The characteristic skin signs occur in four highly stereotyped stages: at birth, patients are born inflammatory vesicles; these change few months later into verrucous patches; later on, the verrucous patches will be replaced with a distinctive pattern of hyperpigmentation; and the fourth stage is characterized by dermal scarring (27).

### 152.5.3 Human Hair Disorders Involving the Keratins and Their Regulators

**152.5.3.1 Monilethrix.** Monilethrix (OMIM 158000) is a condition that affects the hair and sometimes the nails, and is most commonly inherited in an autosomal dominant pattern, though autosomal recessive patterns have recently been reported. It is clinically characterized by dystrophic alopecia that involves most commonly the occipital region of the scalp, but in more severe cases can involve the entire scalp, eyebrows, eyelashes, body hair, and nails (Figure 152-6). Patients may also develop keratosis follicularis and perifollicular erythema. Monilethrix is mostly caused by mutations in the type II hair keratins K81 and K86, and less commonly K83

FIGURE 152-5 Hypohidrotic ectodermal dysplasia.

(28,29). The most common site of mutations was localized to the conserved helix termination motifs of K81, K86 and K83, followed by the helix initiation motifs. These keratins are highly expressed within the hair cortex, and are critical to the normal development of the cortex. Mutations in these keratins result in hairs with a beaded appearance because of a periodic decrease in diameter along the hair shaft (28,29). To date, no mutations linked to monilethrix have been associated with mutations in type I hair keratins.

**152.5.3.2 Pure Hair and Nail Ectodermal Dysplasia.** Several types of pure hair and nail ectodermal dysplasias (OMIM 602032) with either autosomal recessive or autosomal dominant pattern of inheritance have been reported. To date, only mutations in K85, a type II hair keratin that is critical for the normal development of the HF, have been linked to recessive pure hair and nail ectodermal dysplasia. Patients with autosomal recessive pure hair and nail ectodermal dysplasia are characterized by total alopecia and dystrophic nails (Figure 152-7). K85 is mainly expressed in the matrix of the follicle, which might explain the severe phenotype in these patients (30,31).

**152.5.3.3 Autosomal Dominant Woolly Hair.** We and others have recently identified keratin 74, a type II IRS

keratin, as the cause of autosomal dominant woolly hair (ADWH; OMIM 194300) in a four-generation Pakistani family. Patients with ADWH report a slowly growing hair which stops growing at few inches. Clinically they are characterized by dry and coarse woolly hair with normal hair density (32) (Figure 152-8). More recently, Wasif et al. reported mutations in keratin 74 in the setting of hypotrichosis (33). Therefore, within the same family, keratin 74 can cause either woolly hair or hypotrichosis.

**152.5.3.4 Loose Anagen Hair Syndrome.** Loose anagen hair syndrome (LAHS; OMIM 600628) is a sporadic hair disorder but an autosomal dominant pattern of inheritance has been suggested. LAHS is clinically characterized by anagen hairs that are easily plucked from the scalp with no pain. Generally, hair shafts have reduced caliber but are not fragile and not easily broken. It has been proposed that defects in keratin 75, a type II keratin in the companion layer, may underlie LAHS (11,34).

**152.5.3.5 Pachyonychia Congenita Type II (Jackson–Lawler Syndrome).** Pachyonychia congenita type II (PCII; OMIM 167210) is a rare genodermatosis characterized by thickened nails, PPK, natal teeth, and steatocystomas. Although not commonly associated with

FIGURE 152-6 Monilethrix.

FIGURE 152-7 Autosomal recessive pure hair and nail ectodermal dysplasia.

**FIGURE 152-8** Autosomal dominant woolly hair.

a hair phenotype, patients can develop pili torti when keratin 17, an ORS keratin, is mutated (1).

**152.5.3.6 T-Cell Immunodeficiency with Congenital Alopecia and Nail Dystrophy.** T-cell immunodeficiency with congenital alopecia and nail dystrophy (OMIM 601705) is an extremely rare autosomal recessive condition first identified in southern Italy. Patients present with congenital alopecia, nail dystrophy, and severe infections due to T-cell immunodeficiency. Patients usually succumb to the infections during their first year of life. Mutations have been identified in the *FOXN1/WHN* gene, a regulator of keratin expression (35). *FOXN1* plays a critical role in the development of the thymus, the site where T cells mature and become competent, and is a transcriptional regulator of many hair keratin genes.

**152.5.3.7 Tricho-Dento-Osseous Syndrome.** Trichodento-osseous syndrome (TDO; OMIM 190320) is an autosomal dominant condition caused by mutations in the *DLX3* gene, a regulator of keratin expression. This condition is associated with very tightly curled hair, enamel hypoplasia, and diffuse bony abnormalities (36).

## 152.5.4 Human Hair Disorders Involving the Desmosomes

**152.5.4.1 Localized Autosomal Recessive Hypotrichosis/Monilethrix.** Localized autosomal recessive hypotrichosis (LAH; OMIM 607903) is a rare nonsyndromic hair disorder in which patients present with hypotrichosis involving the scalp, chest, arms, and legs. The eyebrows and beard are partially affected, and the axillary hair, pubic hair, and eyelashes are normal. We and others have identified mutations in the desmoglein 4 (*DSG4*) gene as the cause of LAH (37). We and others subsequently identified *DSG4* mutations in the setting of autosomal recessive monilethrix (38). *DSG4* is the only desmoglein member expressed in the keratinizing zone of

the hair shaft cortex, overlapping with the expression of the hair keratins K81, K83, and K86 (18). We postulated that abnormal *DSG4* proteins alter the switch from the proliferation to the differentiation of trichocytes, leading to abnormal and premature keratinization of the hair shaft, resulting in beaded hair as part of the phenotype in some cases (37).

**152.5.4.2 Ectodermal Dysplasia/Skin Fragility Syndrome.** Ectodermal dysplasia/skin fragility syndrome (OMIM 604536) is an autosomal recessive genodermatosis that presents clinically with skin fragility (with trauma-induced erosions and blistering), short and sparse hair, PPK, thickened and dystrophic nails, and occasionally hypohidrosis. This condition is caused by mutations in the plakophilin 1 (*PKP1*) gene (38). Examination of patients' epidermis under electron microscopy demonstrated aberrant cytoplasmic distribution of desmoplakin (DSP) and perinuclear aggregation of KIFs, which indicated that loss of *PKP1* led to disruption in DSP distribution and abnormal aggregation of KIFs. Moreover, *PKP1* affects the size and number of desmosomes, keratinocyte cell migration, and the calcium stability of desmosomes (39).

**152.5.4.3 Cardiocutaneous Diseases: Naxos Disease and Carvajal Syndrome.** *DSG2* and *DSC2* are predominantly expressed in the myocardium of the heart. Heterozygous mutations in the *DSG2* or *DSC2* genes have been reported to underlie arrhythmogenic right ventricular cardiomyopathy (ARVC) as their only clinical manifestation (OMIM 107970) (40,41). Disruption of the desmosomal plaque components PKG or DSP results in several hereditary diseases involving not only the heart, but also the skin and hair. Naxos (OMIM 601214) and Carvajal (OMIM 605676) syndromes are autosomal recessive human disorders characterized by woolly hair, PPK, and cardiomyopathy, which result from protein truncating mutations in the desmosomal components PG and DP, respectively (42,43). Two homozygous

mutations in the gene encoding PG were also found to underlie skin fragility accompanied by diffuse PPK and woolly hair, without heart abnormalities. Interestingly, one of these mutations resulted in sparse and woolly hair, whereas patients harboring the other mutation had abundant woolly hair (44). Over 40 human mutations in the DSP gene have been shown to cause either skin or heart disease, or a combination of skin, hair, and heart abnormalities, underscoring its importance for the development and integrity of these tissues. Like PG, DSP mutations can be associated with hair abnormalities, with both woolly hair and alopecia being described (45).

**152.5.4.4 Hypotrichosis and Recurrent Skin Vesicles.** Hypotrichosis with recurrent skin vesicles (OMIM 613102) is a recently described condition with an autosomal recessive pattern of inheritance, first identified in the Pakistani population. Clinically, affected individuals present with sparse scalp, facial, and body hair with fragile hair shafts, as well as recurrent diffuse vesicles involving the scalp and body and non-mucosal surfaces of the body that heal without scarring. The disease was mapped to the DSG–DSC gene cluster on chromosome 18q12.1, and a homozygous nonsense mutation in the DSC3 gene was subsequently identified in all affected individuals (46).

**152.5.4.5 Hereditary Hypotrichosis Simplex of the Scalp.** Hereditary hypotrichosis simplex of the scalp (HHSS; OMIM 146520) is an autosomal dominant disorder with heterozygous nonsense mutations in the CDSN gene (47). Clinically, patients present with hypotrichosis limited to the scalp. CDSN is expressed in the IRS of the HF. Aggregates of abnormal CDSN can be detected around the HF, as well as in the papillary dermis in patients' skin, suggesting that they are toxic to the HF. Thus, the mutant CDSN protein appears to function in a dominant negative manner (47). Recently, homozygous mutations in CDSN have also been reported in the setting of generalized inflammatory skin peeling syndrome, an autosomal recessive skin disorder characterized by superficial splitting of the upper layer of the epidermis (48) (OMIM 270300).

### 152.5.5 Woolly Hair Related to the LIPH/LPAR6 Signaling Pathway

Lipase H (LIPH) encodes a member of the phospholipase A1 family and is required for the synthesis of lysophosphatidic acid (LPA) (49). LPAR6 (also known as P2RY5) encodes the receptor P2Y5, a seven transmembrane G-protein-coupled receptor (GPCR). Recently, it was found that LPA is a ligand for the receptor P2Y5, which explains the similar phenotypes in patients with either P2RY5 or LIPH gene mutations. Moreover, the expression of P2Y5 overlaps with that of LIPH in the HF (50). These data underscore the important role of the LPA/P2Y5 signaling pathway in the normal development of the HF (51). P2Y5 is mainly expressed in the

inner root hair sheath of the HF that arises from the hair matrix and differentiates before the keratinocytes of the central hair matrix. This provides support for the normal development of the hair shaft, and perhaps explains why the hair becomes twisted when LPA/P2Y5 is disrupted, resulting in a woolly hair phenotype. In addition to the scalp hair abnormalities, patients can develop sparse eyebrows, eyelashes, axillary, and body hair, but usually the beard hair is normal.

**152.5.5.1 Autosomal Recessive Woolly Hair and Autosomal Recessive Hypotrichosis.** We and others have recently shown that mutations in LPAR6 and Lipase H (LIPH) are associated with autosomal recessive woolly hair (ARWH; OMIM 278150) and/or autosomal recessive hypotrichosis (OMIM 611452) (50,52). Mutations in both genes result in a clinically indistinguishable phenotype, which can range from woolly hair to hypotrichosis and complete loss of hair (Figure 152-9) (50). Generally, patients initially present with woolly hair, after which approximately 50% will progress to develop hypotrichosis of variable severity with age. Histology is consistent with decreased number of HFs with miniaturization (53).

### 152.5.6 Hair Disorders Related to the Hair Cycle Regulator, Hairless (HR)

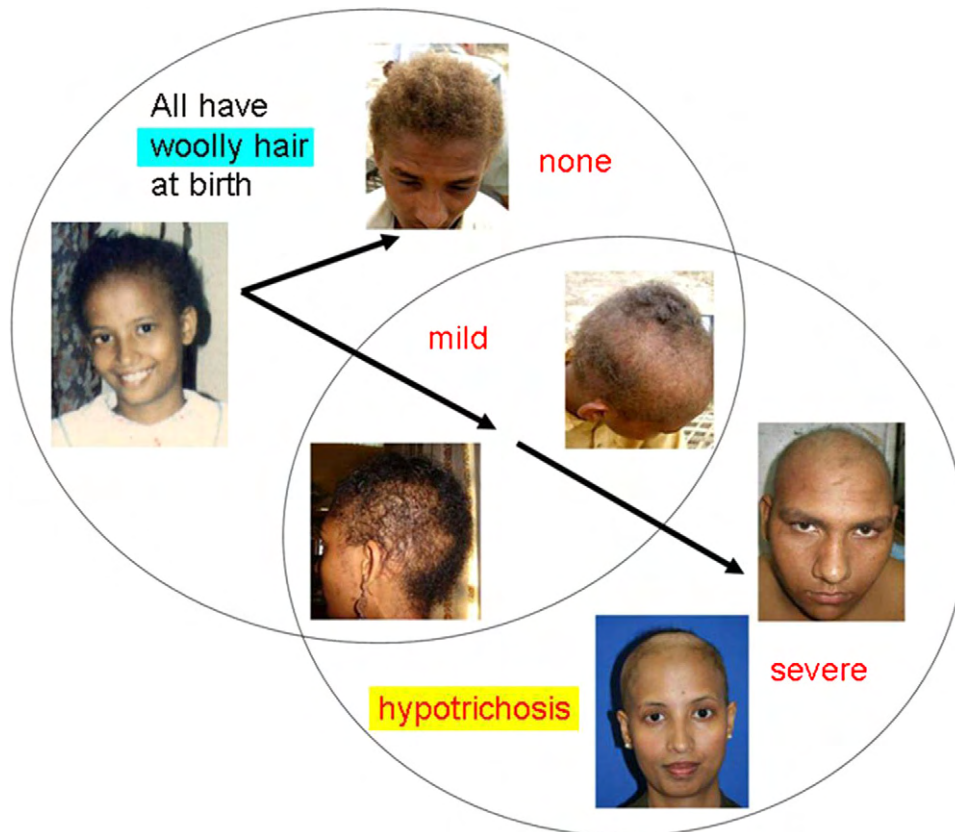

**152.5.6.1 Atrichia with Papular Lesions.** Atrichia with papular lesions (APL; OMIM 209500) is a recessive condition due to mutations in the hairless gene on chromosome 8 (54). Patients initially are born with normal hair density and hair loss occurs few months later, leading to complete alopecia without regrowth of the hair. Patients will later develop milia-like papules involving the face, arms, and knees (54) (Figure 152-10). This condition is frequently misdiagnosed as alopecia areata (AA; see Section 152.9.1). A main distinguishing feature from AA is the presence of milia-like papules in APL. Hairless is expressed in the HF, where it plays a pivotal role in the hair cycle (55). During the regression phase (catagen) the lower part of the HF is degenerated, and under certain stimuli probably related to a cross talk between the DP and the bulge, HF stem cells are activated to regenerate the hair and go back to the anagen phase. Hairless appears to mediate the cross talk between the DP and bulge compartments, leading to the progression of the hair cycle from catagen to anagen. Thus, failure of communication between the DP and the bulge will lead to the arrest of hair growth after the first cycle (56). Mutations in the VDR have been associated with vitamin-D-resistant rickets (OMIM 277440) where patients develop hair loss and milia-like papules similar to APL in association rachitic bone changes during mid to late infancy (57).

**152.5.6.2 Marie–Unna Hypotrichosis.** Marie–Unna hypotrichosis (MUH; OMIM 146550) is a nonsyndromic hereditary hair disease with an autosomal

dominant pattern of inheritance. MUH is clinically characterized by three stages: at birth, affected individuals present with sparse scalp and facial hair, with subsequent development of coarse, wiry, and twisted

hairs in early childhood. Later on during adolescence, affected individuals develop complete hair loss, resembling androgenetic alopecia (AGA). Recently, Wen et al. (58) reported that the 5'-untranslated region

**FIGURE 152-9** Autosomal recessive woolly hair or autosomal recessive hypotrichosis: range of phenotypes and progression of the condition.

**FIGURE 152-10** Atrichia with papular lesions.

(5'-UTR) of the *HR* gene has four potential upstream open reading frames (uORFs), designated U1HR–U4HR. Sequencing of these four uORFs of 19 families with MUH revealed that affected individuals in all 19 families carried heterozygous nucleotide changes within the U2HR (58).

### 152.5.7 Hair Disorders with Mutations in the P-Cadherin (*CDH3*) Gene

**152.5.7.1 Hypotrichosis with Juvenile Macular Dystrophy and Ectodermal Dysplasia with Ectrodactyly and Macular Dystrophy.** Mutations in the *CDH3* gene, encoding P-cadherin, have been shown to underlie two distinct autosomal recessive hereditary diseases in humans. Mutations in *CDH3* were identified in families with hypotrichosis with juvenile macular dystrophy (HJMD; OMIM 601553), which is characterized by sparse hair and weak eyesight due to progressive macular dystrophy of the retina (59). Patients will, on average, be completely blind by the age of 40 years. More recently, mutations in *CDH3* were also identified in ectodermal dysplasia and ectrodactyly with macular dystrophy, termed ectodermal dysplasia and ectrodactyly with macular dystrophy (EEM) syndrome (OMIM 225280) (Figure 152-11) (60). For the same mutation, members within the same family will either have HJMD or EEM. Affected individuals with EEM syndrome show common hair and eye phenotypes with HJMD; however, EEM patients also have the additional clinical manifestation of split-hand/foot malformation (SHFM), suggesting crucial roles for P-cadherin in the development not only of hair and the retina but also of the limb. Mutations in p63, a major transcription factor in epithelial tissues, cause several autosomal dominant

diseases, such as ectodermal dysplasia, ectrodactyly, and cleft lip/palate (EEC) syndrome, which shows phenotypic overlap with P-cadherin mutations in hair and limbs (61). We have shown that p63 colocalizes with P-cadherin in developing HF placode and limb buds during mouse embryogenesis. Furthermore, we have demonstrated that *CDH3* is a direct target gene of p63 (60). Our data underscores the critical role of P-cadherin in the HF, as well as in limb development.

### 152.5.8 Disorders of Pigmentary Hair

**152.5.8.1 Griscelli Syndrome.** Griscelli syndrome is divided into three types: Griscelli syndrome I (GS 1; OMIM 214450) is an autosomal recessive condition characterized by light skin, silvery hair, and neurologic impairment. Mutations occur in the *MYO5A* gene (62). GS 1 is also known as Elejalde syndrome. Griscelli syndrome type 2 (GS 2; OMIM 607624) is the most severe among the three types, inherited in an autosomal recessive pattern, and characterized by light skin, silvery hair, and severe immunodeficiency and lymphohistiocytotic hemophagocytosis, requiring bone marrow transplantation (63). GS 2 is associated with mutations in the *RAB27A* gene. Griscelli syndrome type 3 (GS 3; OMIM) is the most benign of the three types and is characterized exclusively by light skin and silvery hair. Mutations occur either in the *MYO5A* or the melanophilin gene (64). The skin color defect in GS is not due to impaired synthesis of melanin but is secondary to the impaired delivery of the pigment to the appropriate location in the skin and HF.

**152.5.8.2 Chédiak–Higashi Syndrome.** Chédiak–Higashi syndrome (CHS; OMIM 214500) is an autosomal recessive condition associated with mutations in the

FIGURE 152-11 EEM syndrome.

*LYST* gene (65). Clinically, patients present with light-colored skin, silvery hair, photophobia, recurrent infections, and neuropathy. Most individuals will develop an accelerated phase of an uncommon lymphoproliferative disorder characterized by lymphohistiocytic infiltrates, hepatomegaly, hypersplenism, jaundice, and pancytopenia. If not treated with bone marrow transplantation, most patients will die in their first decade of life (66). The most common cause of death is either infection or severe bleeding due to thrombocytopenia. Patients who survive past the first decade will go on to develop progressive neurologic impairment. The gene mutation in CHS affects the synthesis of granules in different types of cells, including immune cells and melanocytes, which explains the clinical features of CHS.

**152.5.8.3 Cross Syndrome.** Cross syndrome (OMIM 257800), also known as Kramer syndrome or oculocerebral syndrome with hypopigmentation, is an extremely rare autosomal recessive condition with unknown genetic defect. Clinically, patients present with light-colored skin, silvery hair, microphthalmia, corneal clouding, spastic paraplegia, and developmental delay (67).

## 152.5.9 Disorders Associated with Light-Colored Hair

**152.5.9.1 Albinism.** Albinism is divided into four major subtypes according to different genetic basis and clinical features. Type I oculocutaneous albinism (OCA1; OMIM 606952) and type II oculocutaneous albinism (OCA2; OMIM 203200) most commonly present with light-colored hair. OCA1 occurs secondary to mutations in the tyrosinase gene which is required for the synthesis of melanin, while OCA2 occurs secondary to mutations in the *P* gene which is required for regulating the PH for the normal functioning of tyrosinase. Clinical features associated with albinism include decreased pigment in the eyes, decreased visual acuity, and nystagmus (68).

**152.5.9.2 Hermansky–Pudlak.** Hermansky–Pudlak syndrome (HPS; OMIM 203300) is a rare autosomal recessive disorder, most commonly occurring in the Puerto Rican population, that clinically resembles oculocutaneous albinism, with recurrent episodes of bleeding, granulomatous colitis, cardiomyopathy, kidney failure, and progressive fatal pulmonary fibrosis. At least eight types of HPS exist; HPS3 being the most common, with mutations in the *HPS3* gene (69).

**152.5.9.3 Waardenburg Syndrome.** Waardenburg syndrome (WS) is divided into four types: WS1 (OMIM 193500), WS2 (OMIM 193500), WS3 (OMIM 148820) and WS4 (OMIM 277580). WS1 and WS3 are caused by mutations in the *PAX3* gene, type 2 is caused by mutations in the *MITF* gene, and type 4 is caused by mutations in *SOX10* or the endothelin-B receptor gene (*EDNRB*). All forms of WS are inherited in autosomal dominant pattern. The common clinical features among

all types of WS include a characteristic white forelock with premature graying of the hair, heterochromic irides, and sensorineural deafness (70).

**152.5.9.4 Piebaldism.** Piebaldism (OMIM 172800) is a rare autosomal condition characterized by mutations in the *KIT* gene. Affected individuals are clinically characterized by a white forelock and depigmented skin patches involving one side of the body that do not cross the midline. The gene defect is presumed to cause abnormal migration of melanocytes from the neural crest during development (71).

**152.5.9.5 Phenylketonuria.** Phenylketonuria (PKU; OMIM 261600) is an autosomal recessive condition caused by mutations in phenylalanine hydroxylase. Phenylalanine hydroxylase is required for the conversion of phenylalanine to tyrosine that is required for melanin synthesis. Patients usually have light-colored skin and hair, secondary to melanin deficiency, eczema, epilepsy, and severe neurologic and developmental abnormalities (72).

## 152.5.10 Disorders Associated with Trichorrhesis Nodosa

**152.5.10.1 Netherton Syndrome.** Netherton syndrome (NS; OMIM 256500) is an autosomal recessive genodermatosis caused by mutations in the *SPINK5* gene, which encodes the serine protease inhibitor LEKTI that functions in the formation of the skin membrane barrier. Affected individuals are born with nonspecific generalized erythroderma covered with fine scales. Patients then develop severe atopic dermatitis, hair loss, a characteristic ichthyosis known as ichthyosis linearis circumflexa, and rarely hypernatremic dehydration and failure to thrive. The most common hair abnormality in NS is trichorrhesis nodosa, although trichorrhesis invaginata is diagnostic. The preferred site to examine the hair abnormalities is the eyebrows (73).

**152.5.10.2 Menkes Kinky Hair Syndrome.** Menkes disease (MNK; OMIM 309400) is an X-linked recessive condition caused by mutations in the *ATP7A* gene, encoding a copper-ATPase transporter. Patients with MNK have copper deficiency and clinically present with growth retardation, cerebral and cerebellar degeneration, dementia, seizures, and kinky hair that on light microscopy shows pili torti (see below), moniliform hairs (see below) and trichorrhesis nodosa (74).

**152.5.10.3 Argininosuccinic Aciduria.** Argininosuccinic aciduria (OMIM 207900) is an autosomal recessive condition caused by mutations in the gene encoding argininosuccinate lyase, one of the enzymes in the urea cycle. Affected individuals become symptomatic early after birth and show hyperammonemia, encephalopathy, respiratory alkalosis, convulsions, liver enlargement, dry skin, and brittle hair that reveals trichorrhesis nodosa under light microscopy. It is presumed that the brittle hair is secondary to deficiency in arginine (75).

**152.5.10.4 Citrullinemia.** Citrullinemia (OMIM 215700) is an autosomal recessive condition caused by mutations in the gene encoding argininosuccinate synthetase, which also forms part of the urea cycle. Patients have similar features to those with argininosuccinic aciduria (76).

### 152.5.11 Disorders Associated with Pili Torti

**152.5.11.1 Bjornstad Syndrome.** Bjornstad syndrome (BJS; OMIM 262000) is an autosomal recessive disorder caused by mutations in the *BCS1L* gene. Clinical features include progressive sensorineural deafness, hair loss secondary to pili torti, and hypogonadism. Mutations in *BCS1L* lead to accumulation of reactive oxygen species, to which the hair and ears are sensitive (77).

### 152.5.12 Disorders Associated with Trichoschisis

**152.5.12.1 Trichothiodystrophy.** Trichothiodystrophy (TTD) is a rare autosomal recessive condition in which the hair is brittle, with trichoschisis and a low sulfur and cysteine content. On polarized microscopy, the hair displays an alternating dark and light banding pattern, which is referred to as tiger tail banding. TTD can be clinically divided into several types. To date, three genes have been implicated in the pathogenesis of TTD: *XPB*, *XPD* (mutated in photosensitive TTD), and *TTDN1* (mutated in non-photosensitive TTD). *XPB* and *XPD* are genes which are implicated in xeroderma pigmentosum, but unlike xeroderma pigmentosum, TTD is not associated with increased risk of skin cancer. TTD clinically presents with variable manifestations including cutaneous, neurologic, and growth abnormalities. Several acronyms are used to describe the clinical manifestations of TTD. PIBIDS (OMIM 278730), IBIDS (OMIM 242170), and BIDS (OMIM 234050) stand for: photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature. Other disorders that are listed under TTD include Sabinas syndrome (OMIM 211390), which is an autosomal recessive condition characterized by hair and nail deformities in association with mental retardation; Pollitt syndrome (OMIM 275550), an autosomal recessive condition characterized by brittle hair and nails, mental retardation, and delayed bone age, with or without dental caries; and Itin syndrome (OMIM 258360), also known as TTD with immunodeficiency, an autosomal recessive disorder characterized by brittle hair and nails, and mental retardation in association with neutropenia and immunoglobulin deficiency. The last subgroup of TTD is TTD with intrauterine growth retardation (IUGR), which is characterized by hair abnormalities, severe IUGR with failure to thrive,

developmental delay, recurrent infections, cataracts, and hepatic angioendotheliomas (78,79).

## 152.6 HAIR ABNORMALITIES IN ASSOCIATION WITH METABOLIC DISEASES

### 152.6.1 Acrodermatitis Enteropathica

Acrodermatitis enteropathica (OMIM 201100) is a rare autosomal recessive disorder caused by mutations in the *SLC39A4* gene, encoding an intestinal zinc transporter. It is clinically characterized by intermittent diarrhea; exfoliative dermatitis that is more pronounced periorally, over the finger and toe tips, and in the inguinal area; and alopecia affecting the scalp, eyebrows, and eyelashes (80).

### 152.6.2 Biotinidase Deficiency

Biotinidase deficiency (OMIM 253260) is a rare autosomal recessive condition caused by mutations in the biotinidase gene. Clinically, patients present with seizure as the most common symptom, in association with ataxia, hearing loss, and skin rash with alopecia resembling that of acrodermatitis enteropathica. Early-onset multiple carboxylase deficiency (OMIM 253270) is a similar disorder, caused by mutation in the holocarboxylase synthetase gene (81).

## 152.7 OTHER DISORDERS ASSOCIATED WITH HAIR PHENOTYPES

### 152.7.1 Trichorhinophalangeal Syndrome

Trichorhinophalangeal syndrome type 1 (TRPS1; OMIM 190350) is an autosomal dominant condition caused by mutations in the *TRPS1* gene. TRPS1 patients have sparse scalp hair, bulbous tip of the nose, long flat philtrum, thin upper vermilion border, and protruding ears. Skeletal abnormalities include cone-shaped epiphyses at the phalanges, hip malformations, and short stature (82). Similarly, TRPS type 2 (OMIM 150230) and TRPS type 3 (OMIM 190350) are associated with sparse scalp hair.

### 152.7.2 Keratosis Follicularis Spinulosa Decalvans

Keratosis follicularis spinulosa decalvans (KFSD; OMIM 308800) is an X-linked recessive disorder that presents in early childhood with keratotic follicular papules; progressive alopecia of the scalp, eyelashes, and lateral third of the eyebrows; photophobia; corneal dystrophy; blepharitis in association with hyperkeratosis over the elbows, knees, palms, and soles; and nail dystrophy. Recently, mutations have been identified in the *MBTPS2* gene, involved in lipid regulation in the skin membrane barrier. Ichthyosis follicularis atrichia photophobia (IFAP; OMIM 308205)

is allelic to KFSD and is clinically characterized by noninflammatory spiny excrescences, hyperkeratosis, and non-cicatricial alopecia and photophobia (83).

### 152.7.3 Hidrotic Ectodermal Dysplasia

Hidrotic ectodermal dysplasia (HED; OMIM 129500), also known as Clouston syndrome, is an autosomal dominant condition caused by mutations in the connexin 30 gene. Patients usually present with total alopecia and nail dystrophy. Unlike patients with anhidrotic ectodermal dysplasia, patients with HED have normal sweating (84).

### 152.7.4 Bazex–Dupre–Christol Syndrome

Bazex–Dupre–Christol syndrome (OMIM 301845) is an X-linked dominant disorder of unknown genetic basis. Clinically, it is characterized by congenital hypotrichosis; follicular atrophoderma affecting the dorsa of the hands and feet, the face, and extensor surfaces of the elbows or knees; and the development of basal cell neoplasms by the second decade of life (85).

### 152.7.5 Hypotrichosis–Lymphedema–Telangiectasia Syndrome

Hypotrichosis–lymphedema–telangiectasia syndrome (HLTS; OMIM 607823) in both dominant and recessive forms has been described, caused by mutations in the *SOX 8* gene. Clinically, patients present initially with hypotrichosis with subsequent development of telangiectasias and lymphedema (86).

### 152.7.6 Chondrodysplasia Punctata Type 2

Chondrodysplasia punctata type 2 (CPXD; OMIM 302960), also known as Conradi–Hunermann syndrome, is an X-linked dominant condition caused by mutations in the *EBP* gene, coding for sterol isomerase emopamil-binding protein. Affected individuals present with coarse hair, scarring alopecia, striate keratoderma, atrophic whorls of hyperpigmentation, cataracts, skeletal abnormalities including short stature, and epiphyseal stippling and rhizomelic shortening of bones (87).

## 152.8 HYPERTRICHOSIS

Hypertrichosis describes all forms of hair growth that are excessive for the body and age of the individual, which occur at any site where HFs are present, and are not under the influence of androgens. Inherited hypertrichoses are very rare human disorders, whose incidence as a group has been estimated to be as low as one in 1000 million (18). Here we will divide hypertrichosis conditions into two main groups: the first are conditions

with generalized hypertrichosis and the second are inherited conditions with patchy hypertrichosis.

### 152.8.1 Disorders with Generalized Hypertrichosis

**152.8.1.1 Ambras Syndrome.** Ambras syndrome (AS; OMIM 145701) is a rare form of generalized CH. Affected individuals present with generalized hypertrichosis that is more pronounced over the upper part of the body, face, and ears, in association with abnormal facial features, such as a triangular, coarse face and long palpebral fissures (Figure 152-12). We studied three patients with AS, and defined an 11.5-Mb candidate interval for AS on chromosome 8q, which includes the *TRPS1* gene (82). One of the three patients with AS carries a pericentric inversion with a breakpoint in 8q23.1, which lies 7.3 Mb downstream of *TRPS1*. We found that the expression of *TRPS1* transcript was markedly downregulated in lymphoblasts of the patient (82). We have also detected a significant downregulation of *Trps1* expression in Koala mice. The Koa mice are characterized by excess hair on the muzzle and ears, and carry a 51.5-Mb inversion on mouse chromosome 15, of which the proximal breakpoint lies 791 kb upstream of the *Trps1* gene (82). Taken together, our data implicate a position effect on the expression of *TRPS1*, which underlies the hypertrichosis phenotype in both human and mouse.

**152.8.1.2 Hypertrichosis with Gingival Hyperplasia.** Hypertrichosis with gingival hyperplasia (OMIM 135400) is most commonly inherited in an autosomal dominant pattern. Affected individuals present with generalized hypertrichosis and coarse facial features, including thick lips, wide and flat nasal bridge, large ears, and gingival hyperplasia (Figure 152-13). The genetic basis of hypertrichosis with gingival hyperplasia is unknown, though recently copy number variations (CNVs) in the genome were reported to be implicated in the pathogenesis of the disease. Affected individuals from three Chinese families with autosomal dominant generalized CH with or without gingival hyperplasia were shown to have a heterozygous deletion on chromosome 17q24.2–q24.3 (88). Moreover, a sporadic case of CH with gingival hyperplasia was heterozygous for a duplication of the same region on chromosome 17q (88). Importantly, the *SOX9* gene, a crucial transcription factor for HF development (89), is located approximately 2 Mb downstream of these CNVs. The data raise the possibility that the CNVs close to the *SOX9* gene may also show a position effect on its expression.

**152.8.1.3 Cantu Syndrome.** Cantu syndrome (OMIM 239850) is a very rare genetic disorder of unknown etiology and is characterized clinically by congenital hypertrichosis, cardiomegaly, and bone abnormalities. The inheritance pattern is unclear, although autosomal dominant, autosomal recessive, and spontaneous occurrence

FIGURE 152-12 Ambras syndrome.

FIGURE 152-13 Hypertrichosis with gingival hyperplasia.

have been reported. We have recently identified a 375-kb duplication on chromosome 4q26–27. The region of duplication encompasses three genes: *MYOZ2*, *USP53*, and *FABP2*. *MYOZ2* and *USP53* are known to be highly expressed in cardiac muscle, and we found that *USP53* is expressed in the HF (90).

**152.8.1.4 Barber–Say Syndrome.** Barber–Say syndrome (OMIM 209885) is a rare congenital condition characterized by severe hypertrichosis, mainly on the back and forehead; atrophic skin with hyperlaxity and redundancy; and facial dysmorphism with hypertelorism, ectropion, telecanthus, abnormal and low-set ears, bulbous nasal tip, small teeth, nystagmus, low frontal hairline, and high arched palate (91).

**152.8.1.5 X-linked Hypertrichosis.** X-linked hypertrichosis (OMIM 307150) is a form of hypertrichosis inherited in an X-linked recessive or dominant form, characterized by congenital generalized hypertrichosis that is associated with dental anomalies and deafness (Figure 152-14). The gene mutated in this condition is still unknown but lies on chromosome Xq24–q27.1 (92).

**152.8.1.6 CAHMR Syndrome.** CAHMR (OMIM 211770) is an autosomal recessive condition reported in an Egyptian family. Affected individuals present with congenital cataracts and congenital hypertrichosis that is more pronounced on the upper part of the body, in association with mental retardation (93).

**152.8.1.7 Amaurosis Congenita, Cone-Rod Type with Congenital Hypertrichosis.** Amaurosis congenita, cone-rod type with congenital hypertrichosis (OMIM 204110) is an autosomal recessive form of hypertrichosis characterized by severe retinal dystrophy with visual impairment since birth and profound photophobia in the absence of night blindness. The underlying ophthalmologic pathology suggested a cone-rod type of congenital amaurosis. The ocular defects are accompanied by trichomegaly, bushy eyebrows with synophrys, and excessive facial and body hair with hypertrophied circumareolar hair on the breasts (94).

**152.8.1.8 Hypertrichosis and Acromegaly.** Hypertrichosis and acromegaly is an autosomal dominant form of generalized hypertrichosis. Affected individuals

characteristically present with generalized hypertrichosis and acromegaloid facies with no intraoral lesions or gingival hyperplasia (95).

### 152.8.2 Disorders Associated with Patchy Hypertrichosis

**152.8.2.1 H Syndrome.** The H syndrome (OMIM 612391) is an autosomal recessive disorder characterized by cutaneous hyperpigmentation, patchy hypertrichosis, hepatosplenomegaly, heart anomalies, progressive sensorineural hearing loss, hypogonadism, short stature, hyperglycemia, hallux valgus, and fixed flexion contractures of the toe and finger joints. The clinical diagnosis relies mainly on the presence of hyperpigmentation and hypertrichosis in the thighs. Mutations occur in the *SLC29A3* gene (96).

**152.8.2.2 Winchester Syndrome.** Winchester syndrome (OMIM 259600) is an autosomal recessive condition characterized by multicentric osteolysis, predominantly over the hands and feet, associated with generalized osteoporosis. Radiographically, the osteolysis is accompanied by a characteristic widening of the metacarpal and metatarsal bones. In addition, affected individuals display coarse facial features, corneal opacities, and generalized hypertrichosis. Mutations have been identified in the *MMP2* gene, encoding matrix metalloproteinase-2 (97).

**152.8.2.3 Porphyrrias.** The four types of porphyria that are characterized by patchy hypertrichosis are porphyria cutanea tarda (PCT; OMIM 176100), hepatoerythropoietic porphyria (HEP; OMIM 176100), variegate porphyria (VP; OMIM 176200), and erythropoietic protoporphyria (EPP; OMIM 177000). Both PCT and HEP are caused by mutations in urogen decarboxylase, with the former inherited as an autosomal dominant condition while the latter is inherited in an autosomal recessive

pattern. VP is inherited as an autosomal recessive condition caused by mutations in protoporphyrinogen oxidase. EPP is an autosomal dominant condition and occasionally autosomal recessive, caused by mutations in ferrochelatase (98).

**152.8.2.4 Schinzel–Giedion Syndrome.** Schinzel–Giedion (SGS; OMIM 269150) syndrome is a condition caused by dominant mutations in the *SETBP1* gene. Affected individuals present with severe mental retardation, hypertrichosis, midface retraction, macroglossia, low-set ears, skeletal abnormalities, genitourinary and renal malformations, and cardiac defects (99).

**152.8.2.5 Berardinelli–Seip Syndrome.** Berardinelli–Seip syndrome (OMIM 608594), also known as congenital generalized lipodystrophy, is a rare autosomal recessive metabolic disease characterized by a near absence of adipose tissue from birth or early infancy and severe insulin resistance in association with acanthosis nigricans, hypertrichosis, muscular hypertrophy, hepatomegaly, altered glucose tolerance or diabetes mellitus, and hypertriglyceridemia. Berardinelli–Seip syndrome is caused by mutations in the *AGPAT2* gene, encoding 1-acylglycerol-3-phosphate O-acyltransferase-2 (100).

**152.8.2.6 Warburg Micro Syndrome.** Warburg micro syndrome (OMIM 600118) is an autosomal recessive syndrome characterized by facial hypertrichosis, microcephaly, microcornea, congenital cataract, optic atrophy, hypogenitalism, mental retardation, agenesis of the corpus callosum, hypotonia, and spastic palsy. Mutations have been identified in the *RAB3GAP* gene, encoding the catalytic subunit of the RAB3 GTPase-activating protein complex (101).

**152.8.2.7 Gorlin–Chaudhry–Moss Syndrome.** Gorlin–Chaudhry–Moss syndrome (OMIM 233500) is an autosomal recessive condition characterized by craniosynostosis, flat midface, microphthalmia, conductive hearing loss, hypertrichosis, coarse hair

FIGURE 152-14 X-linked hypertrichosis.

and low frontal hairline, and short metacarpals and phalanges (102).

**152.8.2.8 Ramon Syndrome.** Ramon syndrome (OMIM 266270) is characterized by maxillary fibrous dysplasia, gingival fibromatosis, epilepsy, neurodevelopmental delay, hypertrichosis, and growth retardation (103).

**152.8.2.9 Zimmermann–Laband Syndrome.** Zimmermann–Laband syndrome (ZLS; OMIM 135500) is an autosomal dominant inherited condition characterized by a coarse facial appearance, gingival fibromatosis, hypoplasia of the terminal phalanges and nails of hands and feet, hypertrichosis, hepatosplenomegaly, and mental retardation. The genetic basis of ZLS is unknown but has been reported in the setting of translocations including t(3;8) and t(3;17) (104).

**152.8.2.10 Cornelia de Lange Syndrome.** Cornelia de Lange syndrome (CDLS1; OMIM 122470) is an autosomal dominant multisystem malformation syndrome characterized by microcephaly, long philtrum, facial dysmorphism, bushy eyebrows with synophrys, anteverted nares, maxillary prognathism, thin lips, upper limb defects, and hypertrichosis, in association with prenatal and postnatal growth and mental retardation. Mutations have been found in around 50% of individuals and they occur in the *NIPBL* gene, which encodes a component of the cohesin complex (105).

**152.8.2.11 Leprechaunism.** Leprechaunism (OMIM 246200), also known as Donohue syndrome, is an autosomal recessive condition characterized by elfin facial appearance; absence of subcutaneous tissue; low-set ears; large hands, feet, and genitalia; decreased muscle mass; acanthosis nigricans; hypertrichosis and pachyderma; and hypoglycemia, with most patients dying within the first year of life. Mutations have been reported in the insulin receptor gene (106).

**152.8.2.12 Cervical Hypertrichosis with Kyphoscoliosis.** Cervical hypertrichosis with kyphoscoliosis (OMIM 117850) is an autosomal dominant condition characterized by excessive hair growth localized to the cervical area, associated with underlying kyphoscoliosis.

Hypertrichosis may also occur at other places along the spine, including the thoracolumbar and sacral regions (107).

**152.8.2.13 Michelin Tire Baby Syndrome.** Michelin tire baby syndrome (OMIM 156100) is an autosomal dominant condition characterized by multiple circumferential deep skin folds on the extremities and gyrus-like on the back, in association with craniofacial anomalies, seizures, mental retardation, esotropia, hemiplegia, congenital heart defect, nevus lipomatosus, and smooth muscle hamartoma, with or without overlying hypertrichosis (108).

**152.8.2.14 Coffin–Siris Syndrome.** Coffin–Siris syndrome (OMIM 135900) is an autosomal recessive condition also known as fifth digit syndrome. Affected individuals show developmental delay, coarse facial features, hypertrichosis, and hypoplastic or absent fifth distal phalanges (109).

## 152.9 GENETICS OF POLYGENIC DISEASES

### 152.9.1 Alopecia Areata

AA (OMIM 104000) is the second most common cause of hair loss in humans, with a lifetime risk of 1–2%. AA affects about 5.3 million people in the United States alone and shows a broad range of phenotypes from a limited (patchy) non-scarring hair loss on the scalp only to complete hair loss on the whole body, known as alopecia universalis (Figure 152-15). There is no permanent organ destruction, and regrowth of the hair remains possible. Histologically, all types of AA are characterized by the presence of a diffuse lymphocytic infiltrate around the HF bulb sparing the bulge, the site where HF stem cells reside. AA is a tissue-specific autoimmune disease, but its molecular mechanism remains largely unknown. Under normal circumstances, the HF is an immune-privileged organ that expresses low levels of major histocompatibility complex (MHC) proteins (110). The genetic basis

**FIGURE 152-15** AA. Left: Limited (patchy) non-scarring hair loss on the scalp. Right: Complete hair loss on the whole body (alopecia universalis).

**FIGURE 152-16** Androgenetic alopecia.

of AA is largely unknown. We recently performed a genome-wide association study (GWAS) on patients with AA and identified several loci that are implicated in the pathogenesis of AA (111). A region of strong association resided in a region of linkage disequilibrium containing genes, the ULBP gene cluster, that encode activating ligands of the natural killer cell receptor NKG2D. We discovered that these ligands are expressed in AA lesional scalp and are markedly upregulated in the HF dermal sheath during active disease. Our findings place AA within the context of shared pathways among autoimmune diseases and implicate a novel disease mechanism, the upregulation of NKG2D ligands, in triggering autoimmunity. Other loci we identified include: *CTLA4*, *IL2/IL21*, *IL2RA* (CD25), *Eos* (*IKZF4*), *ERBB3*, syntaxin 17 (*STX17*) and peroxiredoxin 5 (*PRDX5*). Interestingly, many of these genes have been implicated to play some role in immune regulation.

### 152.9.2 Androgenetic Alopecia

AGA (OMIM 109200) is characterized by shortened anagen phase and HF miniaturization, and is the most common form of hair loss, affecting approximately 40% of men and women (Figure 152-16). AGA is also known as male-pattern baldness in men and female-pattern hair loss in women. Although genetic variations in or close to the androgen receptor have been linked to AGA (112), until recently not much else was known about this common condition. It was recently shown that the single nucleotide polymorphism (SNP) rs1160312 is associated with AGA. This variant lies on chromosome 20 between the *PAX1* and *FOXA2* genes (113). It is still yet unclear whether this variant itself or some other variant nearby is affecting the expression of either gene leading to AGA. With the advance of genetic techniques, such as whole-genome sequencing, it will be possible to pick up many rare variants that were missed with other techniques, and such variants may help us better understand common conditions such as AGA.

## ACKNOWLEDGMENTS

We appreciate input from Drs Claire Higgins and Rita Cabral at Columbia University and Dr Yutaka Shimomura at Niigata University. Supported in part by USPHS/NIH grant RO1AR44924 from NIAMS (to A.M.C.) and the skin Disease Research Center at Columbia University (P30AR44535).

### Biographies

**Dr Kurban** is Assistant Professor of Dermatology, Biochemistry, and Molecular Genetics at the American University of Beirut, Lebanon (as from July 2011). He achieved his MD in 2004, qualified as a dermatologist in 2008, after which he worked with Dr Christiano for 3 years; in parallel he has gained another American-board-accredited fellowship in clinical molecular genetics. He has more than 25 peer-reviewed articles.

**Dr Christiano** is the Richard and Mildred Rhodebeck Professor of Dermatology, Professor of Genetics and Development, and Director of Basic Science Research in the Department of Dermatology, at Columbia University. Her interests are in genodermatoses and mainly in hair and nail diseases, in which she has more than 300 peer-reviewed articles and several book chapters.

## Marfan Syndrome and Related Disorders

*Reed E Pyeritz*

Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

### 153.1 INTRODUCTION

Several hundred distinct heritable disorders of connective tissue (HDCT) have been described phenotypically. Each is presumed to be due to a mutation in a single gene because of the inheritance pattern in families, or evidence that a component of the extracellular matrix (ECM) is abnormal. Mutations could occur in a structural gene for a macromolecule, a gene specifying one of the many post-translational modifications that components of the ECM undergo, a gene encoding a growth factor or a growth factor receptor, and so forth. The upper bounds of the number of HDCT and the number of constituents of the ECM are unknown but are clearly not identical; numerous clinically distinct disorders are due to different mutations in the same gene. Some of these conditions are discussed in this chapter and others are reviewed elsewhere.

For much of the twentieth century, knowledge of the ECM evolved at a seemingly leisurely pace that belied the amount of effort expended by anatomists and biochemists. Application of the techniques of molecular genetics markedly hastened the pace of discovery. Not so long ago, the ECM was parsed simply into fibrous components and ground substance (essentially everything that was not fibrous). Classification schemes have evolved toward structure or function, but remain unsatisfactory.

Elastic and collagen fibers are common to both approaches. Proteoglycans comprise much of what was previously called ground substance. Many of the components are glycoproteins, a term that encompasses all of the collagens, the fibrillins, the nectins or integrins, and much more. In recent years, the most extraordinary realizations have been how intimately and precisely these macromolecules interact, as well as how much variation there is both in interactions among components and among the ECM and cells in different tissues and

at different stages of development. This chapter reviews the composition, structure, function, and pathobiology of one class of components of the ECM, the extracellular microfibrils.

The classification scheme is completely arbitrary. As more is learned about individual components of the microfibril, it is becoming clear that microfibrils are not simply structural moieties. Some mutations in their major component, fibrillin, seem to have a much greater effect on developmental regulation than on structure.

### 153.2 STRUCTURE AND COMPOSITION OF EXTRACELLULAR MICROFIBRILS

Because of their size and characteristic periodicity, the major collagen molecules were first emphasized in ultrastructural studies of the ECM. Elastic fibers also garnered early attention because of their apparent lack of periodicity and peculiar histological staining properties. However, noncollagen linear aggregates have been recognized in electron micrographs of ECM from diverse tissues for nearly four decades (1). A long structure of 10–14 nm in diameter was consistently found to be associated with elastic fibers from vasculature, lung, and skin (2,3) and was called the microfibril (4) (Figure 153-1).

Microfibrils appeared early in tissues undergoing elastogenesis and seemed to be the scaffolding on which tropoelastin is deposited. Subsequently, structures of similar appearance were found in nonelastic tissues, including the superficial dermis (5) and the ocular zonule (6,7) (Figure 153-2). Were these structurally similar but functionally distinct components of ECMs the same?

The answer began to emerge from the studies conducted by Gibson, Cleary, and colleagues in Adelaide, Australia, and by Sakai and colleagues in Portland,

**FIGURE 153-1** Elastic fiber in longitudinal section. In the upper left are collagen fibers in cross section. The amorphous core of the elastic fiber consists of cross-linked elastin. The microfibrils surround this core. (Courtesy of Douglas Keene, PhD.)

**FIGURE 153-2** Scanning electron micrograph in which the cornea and iris have been removed. The zonules emanating anteriorly and posteriorly from the ciliary bodies are clearly seen. The anterior insertions of the zonules on the lens are also shown to good effect. (x25.) (From Streeten, B. W. (6).)

Oregon. Both groups extracted proteins from ligament and other elastic tissues, using methods designed to eliminate collagen and elastin. They then separated the remaining proteins by gel electrophoresis and prepared antibodies to these potential components of microfibril. Immunohistology of various tissues showed that the 10–14-nm microfibrils<sup>1</sup> from the ECM of all tissues bore compositional as well as morphological similarities (8,9).

Subsequently, numerous protein components associated with the microfibril have been characterized (Table 153-1). Some, such as amyloid P and fibronection, are clearly not integral components of the structure. Part of the difficulty in assigning components is that microfibrils differ depending on the tissue source and stage of development. The fibrillins are the only confirmed components of all microfibrils. Monomers of fibrillin associate head-to-tail to form the basic structure of the microfibril. The latent transforming growth factor- $\beta$  (TGF- $\beta$ )-binding proteins are likely to be integral components of some but not all microfibrils. Microfibril-associated glycoprotein-1 seems to be associated with all microfibrils (Lynn Sakai, personal communication).

<sup>1</sup>The diameter of the microfibril depends on the method of fixation and examination, hence the 10–14-nm designation. Many investigators have settled on 12 nm as the characteristic diameter. These structures are also called elastin-associated or elastic fiber-associated microfibrils, but this ignores their important anchoring function independent of the elastic fiber. In this chapter, the term microfibril refers to this 12-nm microfibril.

### 153.3 FIBRILLINS

Sakai and colleagues (9) isolated a glycoprotein of about 350 kDa and called it fibrillin. Monoclonal antibodies to fibrillin bound to 12-nm microfibrils wherever they occurred in the ECM and did not associate with any other macromolecular structure. Fibrillin has emerged as the principal component of microfibrils from all tissues studied (10). Purified monomers of fibrillin, when allowed to aggregate, attain the beads-on-a-string appearance characteristic of microfibrils (Figure 153-3) (11–13). The biology and biochemistry of fibrillin have been difficult challenges because of the size of the monomer and its high content of cysteine residues and consequent intra- and interchain disulfide bonds. The monomer is synthesized by many cells of the ECM, including fibroblasts, smooth muscle cells, osteoblasts, and perichondrocytes. The initial protein has a leader sequence and a propeptide, which are cleaved before microfibrillar assembly occurs outside the cell. The molecule binds calcium, and removal of calcium by chelation alters the morphology of the interbead domain of purified microfibrils, an effect that is reversible (14,15). Fibrillins are conserved through evolution and are found in primitive organisms. Expression of fibrillins begins early in embryogenesis (16–19).

A gene for fibrillin was partially cloned by independent groups led by Sakai and Ramirez in 1991 (20). The messenger RNA (mRNA) was about 10 kb in length, consistent with a protein of 350 kDa. Both groups mapped a fibrillin gene (*FBN1*) to human chromosome 15q21. Lee

**TABLE 153-1** Constituents of the Extracellular Microfibril

Protein	Gene	Map Locus
Structural components confirmed for all microfibrils		
Fibrillin-1	<i>FBN1</i>	15q21.1
Fibrillin-2	<i>FBN2</i>	5q23.q31
Structural components of some microfibrils		
Latent transforming growth factor- $\beta$ -binding protein 1	<i>LTBP1</i>	2p12–q22
Proteins likely associated with some microfibrils		
Latent transforming growth factor- $\beta$ -binding protein 2	<i>LTBP2</i>	14q24
Fibulin-2	<i>FBLN2</i>	3p25–p24
Microfibril-associated protein-2	<i>MFAP2</i>	1p36.1–p35 (formerly designated MAGP1)
Proteins possibly associated		
Microfibril-associated	<i>MAGP2</i>	12p13.1–p12.3 glycoprotein-2
Microfibril-associated protein-3	<i>MFAP3</i>	5q32–q33.3
Lysyl oxidase (found in elastic fibers but not isolated microfibrils)	<i>LOX</i>	5q23.3–q31.2
Microfibril-associated protein-1	<i>MFAP1</i>	15q15–q12
Latent transforming growth factor- $\beta$ -binding protein 3	<i>LTBP3</i>	11q12
Latent transforming growth factor- $\beta$ -binding protein 4	<i>LTBP4</i>	19q13.1–q13.2

**FIGURE 153-3** Transmission electron microscopy of microfibrils purified from dermal fibroblasts and rotary shadowed. (A) Normal control. (B) Cells from a patient with Marfan syndrome. Note the differences, which are especially striking in the interbead regions. (Courtesy of Cay Kielty, PhD.)

and coworkers (20) also found a second locus for fibrillin (*FBN2*) that mapped to human chromosome 5q23–q31. Corson and colleagues (21) recently identified a third fibrillin locus on chromosome 19p13.3–p13.2. Fibrillin-2 (OMIM 121050) and fibrillin-3 (OMIM 628529) are highly homologous to fibrillin-1 (OMIM \*134797) and co-localize to all microfibrils, with a preference for elastin-associated microfibrils (18).

The entire genomic organization of *FBN1* has been elucidated (22). Its 65 exons are spread over 200kb of chromosome. The open reading frame contains 8,616 nucleotides surrounded by 134-nucleotide 5′- and 916-nucleotide 3′-untranslated regions. The regulatory sequences have not yet been defined in detail. The amino acids of fibrillin-1 are highly conserved among mammals.

The three fibrillins have distinct regions and repeating sequences consistent with the mosaic organization of most structural proteins of the ECM (Figure 153-4). The most extensive region consists of two types of motifs. One comprises 47 repeats, each containing six cysteine residues and most of which are encoded by a single exon (numbers 11–63). The motif of these repeats is highly homologous to epidermal growth factor (EGF); 43 of the repeats contain a consensus sequence for calcium binding, a known function of one class of EGF-like repeats. The second most prevalent motif contains eight cysteine residues and is homologous to a motif in transforming growth factor- $\beta_1$ -binding protein (TGF $\beta_1$ -BP). These sequences are interspersed with the EGF-like motifs along the C-terminal three-fourths of the protein. A

**FIGURE 153-4** Structural and functional motifs of fibrillin-1.

region of high proline content is an unusual motif, as are a number of repeats that diverge slightly from the consensus EGF-like and TGF $\beta$ <sub>1</sub>-BP-like motifs. Additionally, 11 potential sites for glycosylation and one for cell attachment (RGD sequence) occur.

Fibrillin-2 and -3 share this same organizational mosaic. The fibrillins are thus similar to other ECM proteins in certain respects. The EGF-like motifs, in particular, are found in laminin, perlecan, the fibulins, nidogen, and tenascin; the known characteristics of these molecules shed light on the structure of fibrillin. The six cysteine residues form three specific disulfide bonds, creating a stable conformation of three antiparallel  $\beta$ -sheets. Serial repetitions of these units results in a rodlike conformation (23). In other molecules, calcium binding is important for stabilizing this motif and for enabling protein-protein interactions, and evidence suggests this to be the case for fibrillin (15,23–25). Furthermore, evolutionary conservation of many of the noncysteine residues and the occurrence of a preponderance of mutations discovered thus far in the EGF-like repeats lend additional weight to their functional importance [(26); *vide infra*]. There is also accumulating evidence that fibrillins promote cell-matrix interactions (27,28), in part through the TGF $\beta$ <sub>1</sub>-BP motif (29).

In mammals, fibrillin-2 and fibrillin-3 tend to be expressed earlier than fibrillin-1, especially at sites of elastogenesis. The exception is the cardiovascular system, in which fibrillin-1 is deposited first (19). Fibrillin-1 is also expressed preferentially at sites where elastogenesis is minimal or absent. However, fibrillin-1 and -2 are widely expressed in mouse embryos (30,31). Both fibrillins have N- and C-propeptides that require cleavage (32), are extensively modified post-translationally, and participate in complex series of polymerizations and cross-linkings to form the microfibril (33,34). Fibrillin-3 has been inactivated in the mouse (21), which needs to be considered in interpreting the various mouse models of Marfan syndrome (MFS) (*vide infra*).

### 153.3.1 Microfibril-Associated Glycoprotein

Gibson and Cleary purified a number of peptides from microfibrils; some probably represent cleavage fragments of fibrillin and other constituents, but several are clearly

intrinsic components. One, termed microfibril-associated glycoprotein (MAGP; OMIM \*156790), has a predicted molecular weight of 31 kDa based on sodium dodecyl sulfate-polyacrylamide gel electrophoresis. However, sequencing the bovine complementary DNA (cDNA) for MAGP showed that the actual amino acid sequence predicts a peptide of only 21 kDa. The C-terminal region is rich in cysteine and basic residues, whereas the N-terminus contains acid residues and proline. The human cDNA for MAGP, encoded by *MFAP2*, has eight coding exons and two alternatively spliced 5'-untranslated exons. *MFAP2* maps to the region 1p36.1–p35.

### 153.3.2 Microfibril-Associated Protein-1

The size of microfibril-associated protein-1 (MFAP1; OMIM 600215), when partially purified from microfibrils, was 56 kDa. Subsequently, the cDNA was cloned, and the amino acid sequence predicted a protein of 54 kDa. The 2.1-kb mRNA is expressed widely in chick embryo tissues, especially those producing elastic fibers. The human counterpart maps to 15q12–q21, intriguingly close to *FBN1*.

### 153.3.3 Microfibril-Associated Protein-3

This protein has no homologies with known proteins. Monoclonal antibodies against the recombinant protein react with ocular zonules (35). The map location in the human for this simple gene (only two translated exons) is 5q32–q33.2, close to but clearly distinct from *FBN2*.

### 153.3.4 Fibulin-2

Fibulin-2 immunolocalizes to microfibrils. Whether it is an integral structural component or only associated remains unclear. If the latter, the association seems to have some specificity; fibulin-2 binds to particular cleavage fragments of fibrillin-1 (36). The gene for fibulin-2, *FBLN2*, maps to 3p24.2–p25 in the human.

### 153.3.5 Other Components of the Microfibril

Lysyl oxidase (OMIM \*153455), a copper-requiring enzyme crucial to interchain bonding of elastin, is one of

(A)

(B)

**FIGURE 153-5** Immunofluorescent histopathology of the dermal-epidermal junction (top of each figure) and dermis (x100). (A) Biopsy of the posterior upper arm from a 35-year-old woman with no evident connective tissue disorder. (B) Biopsy of the posterior upper arm from a 33-year-old woman with classic Marfan syndrome. The section was incubated with a mouse monoclonal antibody to fibrillin-1 (gift of D. Lynn Sakai) and washed, and the bound antibody visualized with goat antimouse IgG conjugated with FITC. (Sections prepared by Grant Anhalt, MD.) SD, standard deviations; US/LS, upper segment-to-lower segment ratio.

the amorphous components of the elastic fiber and probably has a specific association with microfibrils. Emilin (OMIM \*130660), a 115-kDa glycoprotein, may have a role in the interaction of elastin and the microfibrils. It was originally called gp115. In addition, peptides of apparent molecular weights 25 and 78 kDa have been isolated from microfibrils but remain poorly characterized.

#### 153.4 FUNCTIONS OF MICROFIBRILS

Microfibrils have at least four major functions:

- (1) Microfibrils are formed in sites of elastogenesis (37). However, the mechanisms of elastogenesis are far from clear; for instance, mice that synthesize no fibrillin-1 still form elastic fibers of relatively normal appearance (38), and elastin appears to be deposited in some sites lacking any evidence of microfibrils (LY Sakai, personal communication).
- (2) Because of their location in mature elastic fibers exterior to the amorphous elastin component, microfibrils

also likely play a role in linking elastic fibers to each other, to other components of the ECM, and to cells.

- (3) Microfibrils unassociated with elastin perform anchoring functions of several types. They are the principal component of the ocular zonule and thus hold in place a relatively large structure, the lens (39) (see Figure 153-2). In addition, microfibrils are the major constituent of the so-called oxytalan fibers, which extend perpendicularly from the dermal-epidermal junction into the papillary dermis (Figure 153-5). Along with type VII collagen and other macromolecules, they most likely have a role in stabilizing that important interface.
- (4) Finally, microfibrils bind the latent TGF- $\beta$  complex, serving as a sump to regulate the level of active TGF- $\beta$  at any stage of development and postnatal life.

A variety of other functions are possible. The roles of microfibrils in wound healing, fibrosis and neoplasia have not been explored.

## 153.5 MARFAN SYNDROME (OMIM \*154700): THE PROTOTYPE OF DISORDERS OF MICROFIBRILLOGENESIS AND THE FIBRILLINS

### 153.5.1 Historic Perspective

In 1896, the French pediatrician A. B-J. Marfan described a nearly 6-year-old girl with long, thin fingers and limbs, which he termed *dolichostenomelia* (40). This girl also had multiple joint contractures and developed scoliosis. Several years later, Achard (41) described a patient who had loose-jointedness of the hands, as well as hypognathism and *dolichostenomelia*; this condition was called *arachnodactyly*. In retrospect, neither of these patients may have been affected by what now is called Marfan syndrome (42). Over the next 40 years, other features of the syndrome were coupled with the skeleton. In 1914, subluxation of the ocular lenses was associated with the *dolichostenomelic habitus* (43), although two tall, loose-jointed sibs with *ectopia lentis* had been described many years before (44). The heritable nature of the condition and primary involvement of tissue derived from embryonic mesoderm were first noted by Weve (45), who also associated Marfan's name with the phenotype for the first time, calling the syndrome *dystrophia mesodermalis congenita, typus Marfanis*. The aortic complications of dissection and dilatation were clearly associated with the skeletal findings by Baer and colleagues (46) and by Etter and Glover (47), although reports of congenital heart disease and *arachnodactyly* had appeared previously (48,49). McKusick (50) drew wider attention to the spectrum of the cardiovascular problems encountered in living patients and postmortem specimens. Of more fundamental importance was his labeling of MFS as a heritable disorder of connective tissue, one of the first of a long line of conditions to be so designated. Beals and Hecht (51) described the congenital contractural *arachnodactyly* syndrome and proposed that it was the condition that had affected Marfan's original patient.

Debate continues over whether Abraham Lincoln, who was tall, *dolichostenomelic*, and loose-jointed, was affected by MFS (52–55). The violinist Paganini was unquestionably asthenic and loose-jointed, features he used to enhance his showmanship and virtuosity; whether he had MFS is also uncertain (56). In recent years, several young athletes have died from aortic complications of MFS, some of which were diagnosed, unfortunately, only in retrospect. The death in 1986 of US Olympic Volleyball star Flo Hyman increased awareness of the condition among the general public, athletic coaches and trainers and physicians throughout the world.

Since publication of the 5th edition of this text, considerable progress has been achieved in understanding the etiology, pathogenesis, clinical history, and management of MFS. This chapter and the references herein emphasize the developments of the past few years.

### 153.5.2 Prevalence

Based on crude calculations of the size of the catchment area and the number of Marfan patients in the files of Johns Hopkins Hospital, the prevalence was estimated as 4–6 per 100,000. Since the manifestations of MFS may extend from the limits of normal to the floridly 'classic', in which the diagnosis is unquestionable, the actual prevalence of MFS clearly exceeds this estimate.

MFS occurs in all races and in all major ethnic groups residing in the United States. Relative prevalences in ethnic groups elsewhere are unknown, but cases of MFS have been reported from around the world.

### 153.5.3 Marfan Phenotype and Natural History

MFS can usually be defined on the basis of clinical features and mode of inheritance, despite discovery of the fundamental defect (57). Increasingly, clinicians resort to searching for mutations in the gene encoding fibrillin-1 (*FBN1*). While this can be useful, especially in families in which the specific mutation has been defined, or in which linkage of the classic phenotype to the fibrillin-1 locus (*FBN1*) on chromosome 15 can be confirmed, molecular analysis can also complicate the diagnosis, as will be discussed subsequently. Although many systems are affected in MFS, the cardinal features defining the classic phenotype appear in four systems; the skeletal, the ocular, the cardiovascular and the central nervous system (58). Table 153-2 summarizes the most prevalent manifestations observed in 50 consecutive patients, published before the dura was known to be affected.

In 1972, the records of 257 Marfan patients at Johns Hopkins Hospital were examined for life expectancy and causes of death (59). The study was performed when medical and surgical therapy had virtually no beneficial impact on patient survival. Survival had fallen to 50% for men at age 40 years and for women at age 48 years, a reduction in expected life span of about 30–40% for both sexes. The mean age of death of the 72 deceased patients was 32 years. The immediate cause of death in more than 90% of cases was a cardiovascular complication. Dissection or rupture of the aorta and chronic aortic regurgitation with congestive heart failure accounted for the vast majority of deaths.

**153.5.3.1 Skeletal Manifestations.** Mean height in MFS is greater than that of either unaffected sibs or the population average for similar sex, age, ethnicity and cultural background (Figure 153-6). At birth, affected children tend to be longer than normal, a discrepancy that persists, although the growth rate is no greater than that of their unaffected peers. Both puberty and the pubertal growth spurt occur about 2 years earlier in MFS (60).

The limbs are disproportionately long compared with the trunk (*dolichostenomelia*). The increased length of the limbs may be estimated if the lower segment length

**TABLE 153-2** Features of Marfan Syndrome in 50 Consecutive Clinic Patients

	No. of Patients Demonstrating Clinical Feature
<i>Ocular</i>	35/50
Ectopia lentis	30/50
Myopia	17/50
<i>Cardiovascular</i>	49/50
Mid-systolic click only	15/50
Mid-systolic click and late systolic murmur	9/50
Aortic regurgitant murmur	5/50
Mitral regurgitant murmur only	3/50
Abnormal echocardiogram	48/50
Aortic enlargement	42/50
Mitral valve prolapse	29/50
Prosthetic aortic valve	5/50
<i>Musculoskeletal</i>	50/50
Arachnodactyly	44/50
US/LS 2 SD below mean for age	36/47
Pectus deformity	34/50
High, narrow palate	30/50
Height >95th percentile for age	29/50
Hyperextensible joints	28/50
Vertebral column deformity	22/50
Pes planus	22/50
<i>Family history</i>	40/47
Additional documented cases of syndrome	40/47
Sporadic cases (presumed new mutations)	7/47
Unclear or unknown pedigree	3/50

SD, standard deviation; US/LS, upper segment-to-lower segment ratio. Adapted from Pyeritz, R. E & McKusick, V. A (386).

(top of the pubic ramus to floor) is divided into the upper segment length (height minus lower segment). This US/LS ratio varies with age during normal growth but, in the person affected by MFS, is usually at least two standard deviations below the mean for age, race, and sex (Figure 153-7). The US/LS ratio may be exaggerated by scoliosis or abnormal kyphosis. Similarly, the arm span-to-height ratio, which usually exceeds 1.05 in MFS, can be confounded by contractures of the elbows.

Arachnodactyly appears in numerous other syndromes and remains largely a subjective feature. Attempts to provide a radiographic criterion by means of the length-to-width ratio of hand bones (metacarpal index) have not demonstrated enough improvement in diagnostic power to justify the time, cost and radiation exposure (61). Simple maneuvers such as the thumb sign (positive if the thumb, when maximally opposed within the clenched hand, projects beyond the ulnar border) (Figure 153-8A) and the wrist sign (positive if the distal phalanges of the first and fifth digits of one hand overlap when wrapped around the opposite wrist) (Figure 153-8B) are helpful

when positive. However, these maneuvers are subject to observer interpretation and may reflect the longitudinal laxity of the hand rather than arachnodactyly.

Longitudinal overgrowth of the ribs produces anterior chest deformity, either depression (pectus excavatum or funnel chest) (Figure 153-9A) or protrusion (pectus carinatum or pigeon breast) (Figure 153-9B) of the sternum. In these cases, the chest is often asymmetrical, with one set of costochondral junctions (usually the left) protruding more than the contralateral set. The anterior chest deformity can change markedly during the course of growth of the ribs. A mild pectus excavatum in an infant can worsen in a matter of a few years, become asymmetrical, or convert to a carinatum defect. Joint laxity is frequently present but has little diagnostic specificity. The fingers, wrists, elbows, and knees (genu recurvatum) are commonly hyperextensible. Laxity of the carpal ligaments produces flat feet (pes planus with or without calcaneoplanovalgus) in at least one quarter of patients (62) (Figure 153-10). Some patients demonstrate limited extension or unequivocal congenital contractures, usually of the fingers or elbows, which may coexist with laxity of other joints. Joint laxity can lead to recurrent dislocation, most commonly of the first metacarpal-phalangeal joint and the patella. Laxity of the ankle and foot produces instability and various foot deformities, in addition to pes planus. While most patients have adequate foot function, if severe deformity is ignored at an early age, lifelong gait disturbances can result. Pes cavus may occasionally develop. Joint laxity of the fingers, elbows, and knees often lessens with age. In later life, degenerative arthritic changes are commonplace in joints that were once particularly lax. Complaints of joint discomfort are common in patients with MFS of all ages (63).

Scoliosis may occur at one or multiple sites along the vertebral column and generally worsens during periods of rapid growth, such as early adolescence (64). From a study of a relatively unbiased clinic population, the prevalence of severe scoliosis is about 10% (64), considerably less than was suggested in earlier studies. Scoliosis first noted in infancy tends to progress relentlessly (65). Mild degrees of curvature can best be appreciated clinically by observation of erect patients from behind as they bend forward at the hips with arms at full length and palms in contact; either the curve of the vertebral column will be more evident, or one shoulder will be higher than the other (Figure 153-11). A leg-length discrepancy of greater than 2cm occurs in about 5% of patients and correlates with severity of scoliosis (66,67). Thoracic scoliosis is usually obvious on the routine chest radiograph. Kyphosis of the thoracic or thoracolumbar region often accompanies scoliosis, but in many patients, even in the absence of scoliosis, a straightening of the usually mild thoracic kyphosis (straight-back syndrome) or even a thoracic lordosis occurs, resulting in a reduced anteroposterior diameter of the chest (Figure 153-12).

**FIGURE 153-6** Growth curves for stature in the Marfan syndrome. Plots of height versus age of males (A) and females (B) not treated with hormones. The curves are fifth-degree polynomial least-squares regressions from the mean  $\pm$  1 and 2 SD. The thin curves are for comparison to the general population's 50th (A) and 95th centile (B). (From Erkula, G., et al. (60).)

Cervical scoliosis and kyphosis can be associated with neck pain (68). Spondylolithesis in the lumbosacral region occurs in some young patients at a higher frequency than expected in the general population (64). Atlantoaxial rotatory instability has led to subluxation in a few cases (69).

Congenital dislocation of the hip is probably of increased frequency, but is not a common problem (70). An abnormally deep socket of the hip joint (protrusio acetabuli) occurs in about 30–50% of Marfan patients (71,72) (Figure 153-13), occasionally causing disability (64). As patients survive longer, degenerative arthritis of the hip, knees, and other joints will become more common complaints.

The occurrence of several of the above musculoskeletal features in the same individual should prompt consideration of MFS (73), although the sensitivities and specificities of various combinations of features have not been investigated.

The hard palate is often narrow and highly arched and causes tooth crowding. Retrognathia is common and contributes to dental malocclusion and a predisposition to obstructive apnea and sleep disturbance (74–77).

Studies of bone mineral density in MFS have come to conflicting conclusions. Observations before the early 1970s are unreliable because of potential confusion with homocystinuria, in which osteoporosis clearly occurs.

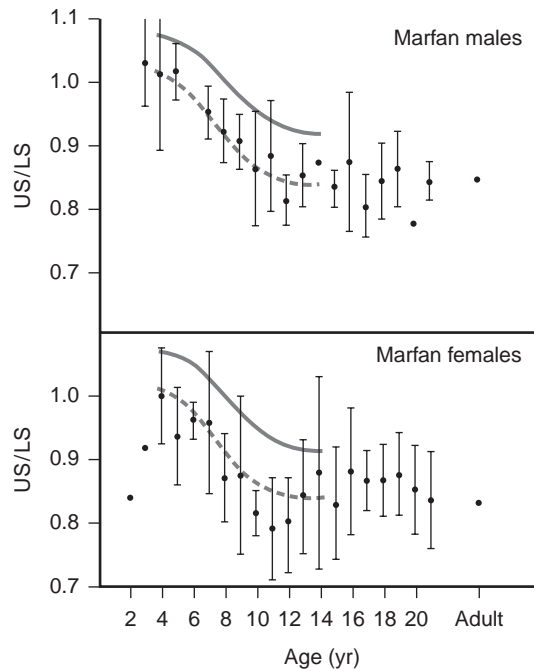

FIGURE 153-6—cont'd

One investigation used dual-energy X-ray absorptiometry of the lumbar spine, proximal femur and total body in 17 premenopausal women with MFS. The conclusion was that women with MFS have abnormally low total body and proximal femoral bone mineral density (78). In a study of only the distal forearm by single photon absorptiometry of 10 men and 4 women with MFS, the opposite conclusion was reached (79). However, two women in the latter study had abnormal results. A more recent study found osteopenia in adult males with MFS (78). In another study, dual energy X-ray densitometry showed no difference in bone density at the lumbar spine and the femoral neck between adult women with MFS (mean age 51 years) and controls matched for height and age (80). More recent studies have favored decreased bone mineral density as a pleiotropic feature of MFS (81–83).

As people with MFS live longer, the possibility of an increased risk of fracture should be explored, especially in women.

**153.5.3.2 Ocular Manifestations.** On inspection, patients with Marfan syndrome may have megalocornea and a miotic pupil. The eyes are often deeply set because of lack of retrobulbar fat. Strabismus occurs in 20%, one half of whom have exotropia (84). Studies of corneal shape (keratometry) show that most people with MFS have relatively flat corneas (Table 153-3). The anterior surface of the iris has a smooth, velvety appearance and transilluminates in about 10% of cases. Typically, the dilator muscle is poorly developed leading to a miotic, difficult-to-dilate pupil.

The diameter of the lens is often smaller than normal; a dislocated, microspherophakic lens occurs in 3%

**FIGURE 153-7** Upper segment-to-lower segment ratios (US/LS) in Marfan syndrome. The US/LS falls with increasing age through early puberty. Points show the means for white patients grouped in 1-year intervals. Bars show  $\pm 1$  SD. The solid curve is the mean and the dashed curve 2 SD below the mean for unaffected whites. (Adapted from McKusick, V. A. (85).)

of patients and is associated with severe high myopia. Dislocation of the lens (ectopia lentis) is progressive and occurs in a proportion of cases variously estimated at 50–80%; it is usually bilateral, but may be asymmetrical. Ectopia lentis is often not evident at birth (85). The lens early in life is most commonly displaced superotemporally (Figure 153-14). Most of the zonules remain intact as visualized on slit lamp examination, and accommodation is possible. Subluxation tends to progress early in childhood (age 2–4 years) or early in adolescence (age 9–12 years) (I. H. Maumenee, unpublished observations). Posterior subluxation occurs and is easily missed. The lens in MFS will only rarely dislocate into the anterior chamber; anterior luxation is presumably prevented by the miotic pupil. Detection of minimal lens subluxation at the bedside is enhanced by performing direct ophthalmoscopy two to three feet in front of the subject. Subluxation is suggested by fluttering of the iris (iridodonesis), enhanced by rapid alternating right and left gaze. Any patient suspected of having MFS must undergo an annual slit-lamp examination with the pupils fully dilated. However, because of hypoplasia or aplasia of the dilator muscle, mydriasis may be difficult to achieve, making assessment of minor degrees of lens dislocation difficult. A predisposition to cataracts is becoming more evident as people live longer, with development in the fifth decade common (I. H. Maumenee, unpublished observations).

**FIGURE 153-8** Positive thumb (A) and wrist (B) signs in a 30-year-old man with Marfan syndrome. Arachnodactyly is evident.

**FIGURE 153-9** Pectus excavatum (A) and carinatum (B) in two young adolescents with Marfan syndrome.

**FIGURE 153-10** Pes planus in a man with Marfan syndrome. Note the arachnodactyly and the long narrow foot.

The axial length of the globe may be increased, contributing to myopia, increased risk of retinal detachment (especially with axial lengths of greater than 25 mm), and lens subluxation. Spontaneous retinal detachment has been observed before age 5 years, and the lifetime occurrence risk is around 10%. The prevalence of retinal detachment increases following lens extraction (86).

The range of refractive errors detected in MFS is extremely broad and is not limited to myopia (86). However, myopia is frequent, and may appear early and be severe. While increased axial length of the globe and a dislocated spherophakic lens lead to myopia, a flat cornea leads to hyperopia, counteracting the myopia. Astigmatism is common and tends to be high and oblique.

**FIGURE 153-11** Bedside diagnosis of abnormal curvature of the vertebral column. (Courtesy of Paul Sponseller, MD.)

High degrees of astigmatism may remain incompletely corrected at refraction and lead to reduced visual acuity.

Previously, most cases of glaucoma followed lens surgery; the prevalence in MFS with ectopia lentis was 7.7% and increased to 14.8% when the lens had been removed. In the largest series of MFS reported, glaucoma was present in 2.4% of patients younger than 40 years, and in 12.9% of those 40 years and older. Open-angle glaucoma occurred in nearly half of the younger group but only 30% of the older (87). Primary trabeculodysgenesis occurs in infants with severe manifestations of MFS and is a cause of congenital glaucoma (88).

**153.5.3.3 Cardiovascular Manifestations.** The two most common cardiovascular features of MFS are mitral valve prolapse and dilatation of the proximal ascending aorta. The former may result in mitral regurgitation, while the latter may result in aortic regurgitation and predispose to aortic dissection and rupture. The mean age at death is reduced by 30–40% in persons with MFS: nearly all the precocious deaths result from a cardiovascular complication (59).

**Mitral Valve Prolapse.** About 60% of patients have auscultatory signs of mitral or aortic valve pathology,

**FIGURE 153-12** Thoracic lordosis in Marfan syndrome. This adolescent boy has a reversal of the usual thoracic kyphotic curve, resulting in a reduction of the anteroposterior diameter of the thorax. This type of deformity is present in the 'straight-back syndrome'.

but the rest may have normal cardiovascular physical findings (see Table 153-2). Echocardiography greatly enhances detection of the cardiovascular abnormalities, with concomitant improvement in the ability to diagnose MFS. For example, whereas about one third of these patients have single or multiple systolic clicks or systolic murmurs of presumed mitral origin, echocardiography shows that 50–80% of all Marfan patients have prolapse of at least the posterior mitral leaflet (89,90). The prolapse is often pansystolic, with exaggerated leaflet excursion and thickness, suggesting redundancy of valvular tissue. Dilation of the mitral annulus is common, and calcification occurs in a minority. Mitral valve prolapse may not be clinically or echocardiographically present during infancy but may be noted several years later. The degree of prolapse may worsen with age, and mitral regurgitation may appear and progress hemodynamically in some patients who initially had only prolapse (89,91). Even in children, the mitral regurgitation can become severe enough to warrant valve repair or replacement (92).

**Aortic Root Dilatation.** Transthoracic echocardiography of the Marfan aorta (Figure 153-15) in both children and adults readily shows the diameter of the proximal aorta ('root'). Dimensions that are measured routinely include the aortic annulus, the sinuses of Valsalva (SoV), the supra-aortic ridge, and the proximal ascending aorta.

**FIGURE 153-13** Moderate protrusio acetabulae. (A) Right hip of a patient with Marfan syndrome is shown. Arrows point to the acetabular line (AC) and the arrowhead to the ilioischial line (IL). Note the medial displacement of AC. (B) Normal hip. (From Kuhlman J. E., et al. (72).)

**TABLE 153-3** Corneal Shape in Marfan Syndrome<sup>a</sup>

Age (Yr)	No. of Eyes Measured	Mean Keratometer Reading (Diopter $\pm$ SD)
1–8	37	40.9 $\pm$ 2.4
9–14	28	40.8 $\pm$ 2.3
15	72	41.9 $\pm$ 1.7

<sup>a</sup>Normal adult eyes have mean keratometer readings of 43.7  $\pm$  0.2.

The diameter of the SoV, measured at the level of the aortic valve cusps, is positively associated with age and body surface area in both normal controls and people with MFS (93). In MFS, the SoV diameter is usually, but not always, greater than the upper limit of the normal range (94,95), even in young children (92,96–98). In MFS, dilatation rarely involves the annulus, begins in the SoV, and may remain confined there or progress into the proximal ascending aorta after effacement of the sinotubular junction. Except when dissection occurs, dilation rarely progresses as far as the innominate artery.

Rarely will a person in whom the diagnosis of MFS is strongly suspected on other grounds (skeletal, ocular, and family history) have none of these echocardiographic abnormalities. In a few patients, a technically satisfactory transthoracic echocardiogram is unobtainable because of a severe pectus deformity or emphysema. In these patients, transesophageal echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI) are reasonable alternatives for following the aortic diameter.

**FIGURE 153-14** Ectopia lentis in Marfan syndrome, shown by slit-lamp photography of the lens of a young girl. The lens is dislocated supratemporally. Note the zonules, which are stretched but intact. (Courtesy of Dr. Irene Maumenee.)

The caliber of the proximal aorta increases during childhood in MFS because of both physical growth and dilation. After skeletal maturity, it is safe to assume that further root enlargement in young adulthood is due to pathologic dilation. Remodeling of the aortic root occurs during mid- to late-adulthood, associated with age, gender, blood pressure and body size (99), and this needs to be considered when MFS subjects are followed over the course of their lives. The predictors of the rate of dilation are uncertain. Peripheral blood pressure seems to have little impact, especially since most young people with MFS have brachial blood pressure measurements in the normal range. One study suggested that the pulse pressure determined by applanation tonometry at the carotid artery was positively associated with the diameter of the SoV (100); however, the association was weak and the

**FIGURE 153-15** Cross-sectional echocardiograms, parasternal long-axis view, obtained from a 10-year-old boy. In both frames, the aortic root (ao) in the sinuses of Valsalva is dilated. (A) In systole, the mitral valve (closed arrowhead) is closed and prolapsed into the left atrium (la). (B) In diastole, the open arrowhead points to the thickened anterior mitral leaflet. The aortic valve (closed arrowhead) shows a thin closure line. LV, left ventricle.

methodology is not readily available. When such studies are performed, children with MFS do have increased pulse wave velocity and aortic stiffness (101). The aortic annulus may dilate to a modest degree; but dilation in the region of the sinotubular ridge results in eventual failure of the cusps of the aortic valve to appose. As the aorta continues to dilate, the regurgitant flow increases. The left ventricular response to aortic regurgitation in MFS is qualitatively similar to that with other causes of chronic aortic regurgitation, but the following sequence of events may evolve more rapidly in MFS. The left ventricle dilates to compensate for the increased stroke volume required. Eventually the myocardium begins to fail, and irreversible myopathic changes follow. The end stage, if dissection or rupture of the aorta does not supervene, is death from congestive heart failure (59).

**Aortic Dissection.** This is the most feared complication of MFS. About 90% of acute dissections in MFS begin in the aortic root, just distal to the coronary ostia. Many dissections of the ascending aorta extend, either immediately or in a stuttering pattern over hours or days, to involve the arch and descending aorta, often extending into the iliac vessels. The dissection event is usually sudden, with all of the classic signs and symptoms reflected in series of patients with MFS. However, some dissections occur with few or atypical symptoms, and if the patient survives the acute event, he or she will be left with a chronic dissection of some portion of the

aorta. Cross-sectional echocardiography often displays the ascending aorta for a distance of 4–6 cm above the aortic valve and may be the first clue that a clinically silent dissection has occurred. However, if a dissection is suspected, transesophageal echocardiography, CT, or MRI is the preferred noninvasive approach to diagnosis. Furthermore, the time saved in reaching a diagnosis by noninvasive means enhances survival for patients who require surgery. Roman, Devereux, and colleagues suggested that dilation above the sinotubular junction is a strong predictor of aortic complications (102). In children, the initial aortic diameter was a predictor of both growth rate and complications (96). Other studies suggest that the strongest predictor of dissection of the ascending aorta, aside from the actual caliber of the root, is a history of a dissection in a relative (103).

According to data from the International Registry of Aortic Dissection, half of all aortic dissections in patients less than 40 years of age are due to MFS (104).

The elastic properties of the Marfan aorta are distinctly abnormal. The wall is considerably stiffer than expected from an early age; this is associated with heightened systemic pulse wave velocities (96,97,105,106). MRI and tissue Doppler imaging enable determination of aortic distensibility (107,108). The more stiff the aorta, and the larger the diameter, the more likely that the aortic root will dilate progressively (109). Investigations are needed to define which indices of aortic

elasticity are both prognostically useful and easily determined noninvasively.

The dilated ascending aorta is more susceptible than the undilated aorta to traumatic dissection or rupture. Numerous cases of dissection or rupture, often associated with sudden death, have occurred in persons with MFS while they were exercising (110) or when they were involved in relatively minor deceleration injuries in automobile accidents.

The risk of severe cardiovascular complications during pregnancy is unquestionably increased in a woman with MFS. The major issue for counseling and management is to define the risk for the individual patient. Data are derived from two principal sources: case reports and observational series. The latter can be retrospective or prospective. As with many other medical conditions, case reports tend to over-represent complications (111). A summary of 57 publications reporting 99 patients showed that 50% suffered severe events (112). On the other hand, several observational series document over 300 pregnancies in more than 120 women, and the occurrence of severe maternal cardiovascular complications varied between 1% and 6% (112–116). The increased cardiac output that occurs during the midtrimester places greater strain on the dilated ascending aorta than in the non-pregnant condition. The largest retrospective survey from a single institution examined 105 pregnancies in 26 women with MFS (114). Only one death occurred, due to endocarditis in a woman with severe mitral valve disease that predated the pregnancy (85). At the same institution, 21 women were followed through 45 pregnancies and thereafter (116). None with minimal aortic dilation (less than 42mm) had any vascular complication during pregnancy, and echocardiography every 6 weeks showed no further aortic dilation. During mean follow-up evaluation of 6 years in these women, and compared to a group of nulliparous Marfan women of similar severity, none suffered apparent cardiovascular worsening attributable to pregnancy. Two women (one with aortic regurgitation and moderate aortic dilation and one with a pre-existing dissection) suffered acute dissection of the descending aorta during pregnancy.

The chest radiograph is an insensitive technique for detecting early aortic root enlargement or dissection. Dilation of the proximal ascending aorta is visible on the frontal radiograph only when substantial; mild to moderate enlargement is frequently hidden by the vertebral column and cardiac silhouette (Figure 153-16).

On aortography, the dilated Marfan aorta is characteristic (Figure 153-17). The enlargement is symmetrical and begins in the sinuses of Valsalva. Rarely does the dilation extend as far as the innominate artery, and the ascending aorta has a gourd-like appearance when contrast material is injected.

MRI provides superb visualization of the entire aorta and is useful for detecting dilation, dissection, and coarctation (no increased prevalence in MFS) anywhere along

**FIGURE 153-16** Normal chest radiograph in the presence of aortic root dilation. The proximal aorta of this 28-year-old woman affected by Marfan syndrome measured 4.8cm, nearly 50% greater than normal. This enlargement is hidden by the cardiac silhouette.

**FIGURE 153-17** Aortic root dilation in Marfan syndrome. The sinuses of Valsalva are symmetrically dilated to a moderate degree in this 37-year-old woman.

the vessel and its major branches (Figure 153-18). As a method of following the course of aortic problems (other than simple dilation of the root), especially postoperatively, CT and magnetic resonance angiography are optimal, but magnetic resonance (MR) avoids repeated radiation exposure.

**Other Arterial Involvement.** Elastic arteries besides the aorta can be clinically affected in MFS. Involvement of cerebral arteries may rarely produce intracranial hemorrhage from aneurysm rupture (117), but asymptomatic aneurysms are certainly more common, but of unknown prevalence (118,119). One study from a large

**FIGURE 153-18** Magnetic resonance imaging of the Marfan aorta. T1-weighted images (A–C) show that flowing blood gives no signal, and the lumen of vessels is black. (A) Parasagittal view, showing the gourd-shaped aortic root and ascending aorta. (B) Axial view through the aortic root and mid-descending thoracic aorta; the aortic root is somewhat elliptical and measures 53 mm 61 mm. (C) Axial view through the proximal aortic arch and proximal descending thoracic aorta, showing a type I aortic dissection. (D) Coronal section through the ascending aorta and left ventricle collecting data gated to the cardiac cycle; flowing blood gives a light image. Turbulence from aortic regurgitation in this patient generates a dark image into the left ventricle.

Marfan clinical program found no examples of symptomatic intracranial aneurysm (120). Dissection of both intracranial and extracranial cerebral vessels does occur in Loeys–Dietz syndrome and other disorders of TGF $\beta$  receptors, which have been confused phenotypically

with Marfan syndrome in the past (121). Similarly, coronary, pulmonary, and peripheral arteries can show medial degenerative changes similar to the aorta (122), but reports of complications are few (123–129). Whether the abdominal aorta will show a heightened

(A)

(B)

**FIGURE 153-19** Dural ectasia in Marfan syndrome. (A) Axial computed tomogram through the sacrum and ilia showing considerable enlargement of the neural canal and thinning of the vertebral bone. In addition, large meningoceles emanate from the neural foramina bilaterally. The patient was a 34-year-old man. (B) Magnetic resonance image in the sagittal plane showing ectasia of the sacral neural canal and a large anterior meningocele. The patient was a 23-year-old woman.

predisposition to dilation as patients with MFS age is an open question.

**Ventricular Function.** Anecdotal experience shows that some patients with MFS, who do not have abnormalities of valve function or any other risk factor, do have diminished left ventricular function. Fibrillin is present in the myocardium, and certain mutations could predispose to impaired systolic, diastolic, or generalized contractility. Alternatively, some patients with MFS might also harbor a separate mutation for dilated cardiomyopathy. Studies addressing these points have involved relatively few subjects, and the results are conflicting (130,131).

**Electrophysiology.** No typical electrocardiographic (ECG) abnormalities occur. Changes may result from chronic valvular regurgitation, but usually after these lesions are clinically recognizable. Axis deviations occur because of rotation of the heart by severe pectus excavatum or thoracic lordosis. Some patients have dysrhythmia, usually supraventricular but occasionally ventricular in origin. Mitral regurgitation promotes left atrial enlargement, which in turn predisposes to atrial fibrillation. Patients should always be questioned about palpitations and light-headedness or near syncope, at rest and with exercise. Any symptoms of more than trivial

nature should prompt further evaluation, generally by 24-hour or event ECG monitoring.

**153.5.3.4 The Dura.** Ectasia of the caudal dural sac is a common finding, evident on radiographs of the lumbosacral spine as bony erosions of the neural foramina and anteroposterior scalloping of vertebrae, and on axial CT or MRI scans as a widened neural canal (132–137). An extreme manifestation is an intrapelvic meningocele (Figure 153-19), which may present as a pelvic mass and be confused with an ovarian cyst or tumor (138). Dural ectasia is positively associated with reports of back pain in MFS (132,133,139). Criteria for detecting dural ectasia by MRI or CT include a wider dural sac below L5 than above L4; the presence of anterior sacral meningocele; in the adult, a diameter of the L5 nerve root of greater than 6.5mm; and scalloping of the S1 vertebral body (132,133). The frequency of dural ectasia is 70–90% (134,140). The signs of dural ectasia are often present in childhood, and the severity increases with age (140). An increased size of the dural sac at L3 and S1 was 95% sensitive and 98% specific for MFS (141).

Enlargement of the cranial subarachnoid spaces is common in MFS and is evident as enlarged perivascular (Virchow-Robin) spaces, cranial cisterns, and optic nerve

sheaths. The dura may be extremely thin and fragile when manipulated. Dural ectasia is usually asymptomatic but should be in the differential diagnosis of a Marfan patient with low back pain, lower radicular pain, or leg weakness (142). Chronic headache, especially one that worsens on upright posture, should suggest either a large pelvic meningocele, which acts as a sump for cerebrospinal fluid (CSF), or a dural tear with persistent leakage of CSF (143–145). The presence of dural ectasia should be considered when administering spinal or epidural anesthesia to any patient with Marfan syndrome (146).

**153.5.3.5 The Skin and Integument.** The predominant abnormality of the skin is the stria atrophica, most commonly found over the anterior shoulders, lumbar region, and lateral hips (Figure 153-20). Striae gravidarum can be marked in women with MFS. The skin is otherwise not unusually fragile or susceptible to bruising or poor healing, but may be hyperextensible. Hernias frequently occur, especially in the inguinal region (147). They may appear in early childhood, and a history of multiple repairs is not uncommon. Congenital diaphragmatic and paradiaphragmatic hernias have been reported (148,149).

**153.5.3.6 The Pulmonary System.** Some patients, usually those with severe MFS evident as infants, have cystic lung disease. If the mouse model of MFS is analogous to the human condition, these cysts are not degenerative, but developmental, due to overactivity of TGF- $\beta$  (150). Usually, the cysts, or bullae, are not detected until a pneumothorax occurs. Spontaneous pneumothorax occurs in about 5% of Marfan patients (151). Symptoms are typical of pneumothorax in the general population, specifically ipsilateral chest pain, sudden dyspnea, and tachycardia (152).

Some patients have markedly reduced total lung capacity and residual volume ascribable to deforming

kyphoscoliosis or pectus excavatum. Even in patients without thoracic distortion, forced vital capacity is consistently less than predicted based on height. However, the use of a more accurate predictor of thoracic size, such as the sitting height, shows that static lung volumes in the absence of severe scoliosis and pectus excavatum are not markedly abnormal (153). One study of a small number of young patients suggested an increased prevalence of bronchial hyperreactivity in the absence of clinical signs of asthma (154).

The prevalence of sleep-disordered breathing is probably not as high as suggested (74,75), but the patient (or spouse) should be questioned directly about snoring, nocturnal periodic breathing, and daytime hypersomnolence, especially in the presence of marked retrognathia (77,155). The sleep disturbance is usually obstructive and can be due to craniofacial restriction and laxity of the upper and middle airway that becomes evident only with relaxation of the skeletal muscles.

**153.5.3.7 The Skeletal Musculature.** Many, but by no means all, patients with MFS have a paucity of skeletal muscle, which contributes to their asthenic habitus. Typically, strength is not abnormal. My personal observation is that many of these children and adolescents cannot hypertrophy their muscles with exercise (not that this is ever encouraged!) and the Marfan mouse model clearly has a skeletal myopathy (154). Rarely, muscle weakness can affect respiratory function (156).

**153.5.3.8 The Central Nervous System.** It has been assumed that people with MFS have no impairment of cortical function. Indeed, 30 consecutive school-age clinic patients had average intellectual and gross motor development. However, one-half of these young patients had one or more neuropsychological deficits, including

**FIGURE 153-20** Striae atrophicae of (A) the hip of an 8-year-old girl, and (B) of the anterior shoulders in a 27-year-old man with Marfan syndrome.

learning disability, attention-deficit disorder with or without hyperactivity, neuromaturational immaturity, and verbal-performance discrepancy (157). Joint laxity of the hand and wrist contributed to the latter deficit, but the pathogenesis of the rest of the problems is obscure. Others have found problems with tasks requiring sustained visual attention and visual construction abilities; difficulties could not be explained simply on the basis of reduced visual acuity (158).

A number of single cases of psychiatric disturbance in patients with MFS have been published (159), but the likelihood is that these occurrences are coincidental. Many patients have difficulty dealing psychologically with the complications of MFS, their management, and their effect on lifestyle (160).

### 153.5.4 Pathology

**153.5.4.1 Gross Pathology.** Numerous reports of autopsies of patients affected by MFS appear in the older literature (see McKusick (85) for review). The aorta dilates in its most proximal region, the sinuses of Valsalva. The dilation is symmetrical and may extend above the sinotubular junction. The diameter of the ascending aorta usually returns to normal before the innominate artery, unless a dissection is present. Dilation of the sinotubular junction, at the upper aortic valve attachments, results in failure of the cusps to coapt.

When dissection of the aorta occurs, the entry tear in the intima is frequently several centimeters above the aortic annulus, in the area of greatest dilation. The dissection can either progress antegrade no farther than the arch, progress through the arch into the descending aorta, or extend retrograde. In the latter case, attachments of the valve cusps may be torn, coronary ostia may be occluded, or rupture into the pericardial sac producing tamponade may occur. Any dissection can undergo rapid or gradual evolution. Intimal tears in the absence of dissection are common in the dilated proximal ascending aorta.

The valve cusps are usually diaphanous and redundant, and the mitral valve and annulus are susceptible to calcification. Fenestrations occur in a minority of aortic and mitral valve cusps. The aortic and mitral valves are susceptible to the development of bacterial endocarditis. The proximal pulmonary artery is usually mildly dilated, but pulmonic regurgitation is uncommon. Aneurysmal dilation of coronary arteries has been reported but is uncommon. The coronary ostia may be abnormally high in the aortic root because of root dilation.

No specific changes occur in the atria, ventricles, or myocardium that are not attributable to the effects of chronic valvular regurgitation. Several patients have had clinical congestive heart failure out of proportion to their valvular disease; in these cases, the existence of a cardiomyopathy associated with MFS has been suggested. Histopathological studies of such patients are lacking.

Reports of gross ocular pathology are few, and little can be said other than that the lenses tend to dislocate superiorly, the globes tend to be elongated in the anteroposterior direction, and the corneas are flatter than normal. Published reports of gross pathology of bone, ligaments, and tendons show no particular abnormalities.

**153.5.4.2 Histology and Ultrastructure.** The aortic and mitral valves usually show myxomatous degenerative changes. The aortic wall characteristically shows changes in the medial layer. The elastic fibers become progressively swollen, fragmented, and reduced in number as the aortic diameter increases (Figure 153-21). Lacunae appear in the media, which are filled with basophilic proteoglycan. The term *cystic medial necrosis* has been applied to these histological changes, but it is a misnomer and its use should be discouraged. Neither necrosis nor cysts are present. These histopathological features are also seen in aortas from non-Marfan patients who had hypertension or aortic valve disease, and to a lesser degree may be a concomitant of aging. The most reasonable explanation is that the histopathology indicates injury and repair regardless of the cause of the injury (161). The changes are similar to those seen in experimental copper deficiency and lathyrism in animals (162). Electron microscopic examination confirms focal elastin fiber degeneration and abnormalities of collagen fibers. The medial smooth muscle fibers appear shrunken, and their basement membrane is greatly thickened. Arteries elsewhere in the body may show evidence

**FIGURE 153-21** Medial degeneration of the aorta in Marfan syndrome. Note the fragmentation and disarray of the darkly stained elastic fibers (von Geisen stain).

of medial disorganization, but less than that present in the ascending aorta. Mouse models of MFS has enabled an investigation of how abnormalities in arterial walls evolve over time (39; *vide infra*). The early changes of microcalcification, intimal hyperplasia, and disorganized ECM – all associated with signs of adventitial inflammation – prompted re-examination of human pathological specimens. Dietz and colleagues (27) observed similar histopathological changes in all elastic arteries in autopsy specimens of patients with MFS. ‘Osmiophilic elastolysis’, reported years previously in MFS (122,163), represented the same pathological process. Cartilage biopsies from the iliac crest in three adolescent patients were examined by transmission electron microscopy. The chondrocytes had dilated endoplasmic reticulum, cytoplasmic vacuoles, and increased glycogen stores. Elastic fibers in the skin are seen to be abnormal by ultrastructure and immunohistopathology (164). Ocular zonules show abnormal immunohistological staining for fibrillin-1 (39). Few reports of histological changes in other tissues exist.

### 153.5.5 Genetics

In the vast majority of reported families, segregation of MFS is consistent with autosomal dominant inheritance. Reports of multiple affected sibs with ostensibly normal parents are rare. Based on pedigree analysis, germinal mosaicism is extremely uncommon, but has been confirmed by molecular studies (165–167).

No formal studies of the frequency of sporadic cases or of the evolutionary (or genetic) fitness of MFS have been published. McKusick (85) estimated that 15% of patients had unaffected parents and most likely developed MFS from *de novo* mutation in a parental germ cell. At our medical genetics clinic, neither parent was affected for 41 of 138 consecutive Marfan patients. While various biases influence which patients attend a clinic, these data suggest that sporadic cases account for 15–30% of all patients. The average age of the fathers of sporadic cases exceeds by some 7 years that of fathers in the general population (168); the average age of the mothers of sporadic cases is not as advanced. This paternal age effect has been described in other autosomal dominant disorders, such as achondroplasia.

The extreme interfamilial variability in the Marfan phenotype largely reflects the extensive genetic heterogeneity in mutations of *FBN1* (169). However, intrafamilial variability can be marked; this undoubtedly explains the claims of ‘non-penetrance’ that appear in the older literature. When presumed cases of ‘non-penetrance’ or ‘*formes frustes*’ in families in which other, well-documented cases of MFS occur are examined by sensitive methods (e.g. echocardiography), the Marfan phenotype can usually be diagnosed with confidence. The biological basis of intrafamilial variability in MFS is unclear and is probably multifactorial. Several large families in which

the *FBN1* mutation has been discovered provide opportunities for analysis of mutant allele expression, epistasis, and other explanations (170).

### 153.5.6 Etiology

More than 70 years ago, MFS was hypothesized to be a generalized disorder of the mesenchyme (45). It was one of the original group of conditions classified as a heritable disorder of the connective tissue (50). Peltonen and colleagues in Finland discovered the first linkage relationship, between MFS and anonymous DNA markers on human chromosome 15q (171). Dietz and Francomano and colleagues (172) at Johns Hopkins then refined this linkage through cooperation of the largest pedigree of MFS described in the literature; the strongest linkage, at  $\Theta=0$ , occurs with marker D15S1, which maps to 15q21.1 (172). Subsequently, linkage studies of families throughout the world confirmed this locus. There is no convincing evidence for intergenic heterogeneity in the cause of MFS. Recent reports of mutations in *TGFBR2* in a French family (173) and in several other patients with some features of MFS (174) is intriguing because of the clear role of abnormal TGF- $\beta$  signaling in classic MFS (*vide infra*). However, when clinical descriptions of these subjects are available, they do not warrant a diagnosis of classic MFS. Contemporaneous with the linkage studies, Hollister and Sakai and colleagues pursued the possibility that abnormalities of microfibrillogenesis underlay MFS. Using a monoclonal antibody developed by Sakai against fibrillin, skin from patients with MFS was examined by immunofluorescent microscopy (164). Patients usually had evidence of decreased microfibrils, both at the dermal-epidermal junction (where microfibrils are unassociated with elastin) and coating elastic fibers in the deeper dermis (Figure 153-22). In addition, fibroblast monolayers, grown from the skin specimens, often produced an ECM deficient in microfibrils (Figure 153-23). Byers and Milewicz and collaborators examined the synthesis, secretion, and matrix incorporation of fibrillin in fibroblast specimens from patients with MFS and found one or another defect in all but a few cases (175). Taken together, these results pointed strongly at fibrillin as a candidate protein (and gene) for the cause of MFS. The cloning of *FBN1* (20) and its mapping to the same region of chromosome 15q as MFS (20,176,177) provided additional circumstantial evidence. However, it was the discovery of a *de novo* point mutation in *FBN1* in two unrelated patients with classic severe MFS that clinched the assignment of cause (177). This first mutation, called R239P at the time, substituted a proline for asparagine at a highly conserved residue in a calcium-binding EGF repeat (Figure 153-24). Over the subsequent years, the technical capabilities for identifying mutations in *FBN1* have improved considerably. In the best hands, in more than 95% of cases of classic MFS, a mutation can be found (121,178–180).

**FIGURE 153-22** Elastic fibers of the reticular (deep) dermis from age-matched subjects (x200). (A) Normal control. (B) Person with Marfan syndrome. Note the diminished number of elastic fibers 'coated' with fluorescence, many of which are shortened. Multiple reports of a single French pedigree with 'Marfan syndrome' (28) that maps to chromosome 3p (45) are not inconsistent with this conclusion, because this family does not have Marfan syndrome as defined by international standards (61). (Sections prepared as in Figure 153-5. Antifibrillin monoclonal antibody courtesy of Lynn Sakai, PhD.)

Most mutations in *FBN1* are missense, with those causing premature termination next in frequency. There are relatively few large deletions (181). Genotype-phenotype correlations have been few, with the most well-established being missense mutations of the calcium-binding EGF-like domains in the middle region of the coding sequence, which are more likely to cause a severe phenotype evident at birth. An international database of mutations in *FBN1* is available (182) (<http://www.umd.be/FBN1>; [www.biobase-international.com](http://www.biobase-international.com)). More than a thousand mutations have been reported, most of which are novel.

### 153.5.7 Molecular Pathology

Since 1991, a wide variety of mutations that cause MFS (and related disorders) have been found in *FBN1* (169,183). Initial mutation detection based on single-strand conformational polymorphism or denaturing gradient gel electrophoresis analyses of cDNA proved inefficient (184). Next, genomic DNA was examined by

polymerase chain reaction amplification of each exon, followed by mutation detection enhancement gel heteroduplex analysis. This approach contributed greatly to the total mutations reported to the international database. Most mutations are private (169). Thus there is extensive intragenic heterogeneity at *FBN1*, and no common mutation will emerge. Mutations in regulatory regions of *FBN1* or deep within introns are possible explanations for the failure to identify pathological changes in coding sequences. A few observations are possible. There have been few large deletions. The most common mutation is missense, and most affect calcium-binding EGF-like motifs. A frequent class of mutation is substitution for one of the cysteine residues of the EGF-like motifs. Little can be deduced about genotype-phenotype correlations. Mutations near the C-terminus were initially predicted to cause a milder phenotype, even isolated ectopia lentis. However, severe MFS can result from mutations in this region (185). Severe MFS evident in infancy tends to involve missense mutations in calcium-binding EGF-like motifs encoded by exons 24 through 27, and 31 through

cause a less severe disorder, including the MASS (mitral valve, aorta, skin, and skeleton) phenotype.

### 153.5.8 Pathogenesis

Pathogenesis can be considered at progressively more complex levels, from molecules through tissues to the whole organism (see Chapter 14). This is the most important challenge facing investigators, because only through understanding how this pleiotropic phenotype arises will more effective methods of treatment be devised (189). Studying pathogenesis at complex levels, such as how mutations in *FBN1* cause overgrowth of long bones, is quite difficult in humans. The development of animal models greatly facilitates this process.

**153.5.8.1 Molecular Pathogenesis.** Although the structure of microfibrils is still far from clarified, they are aggregates of multiple structural proteins, the most important of which – the fibrillins – are organized in multimeric fibers composed of dozens and perhaps hundreds of monomers. From a structural perspective, the Marfan phenotype could arise from a defect in any component

32 (186–188). However, mutations in the same exons cause much less severe forms of MFS. Mutations that likely result in early degradation of the mutant protein (e.g. premature chain termination mutations) tend to

**FIGURE 153-25** Some of the published *FBN1* mutations that cause Marfan syndrome. Those labeled above the schematic of the fibrillin-1 cDNA were first identified by collaborators at Johns Hopkins University School of Medicine. (Courtesy of Harry Dietz, MD.)

of the microfibril, in its post-translational processing, or in the construction of the mature structure. As emphasized earlier, there is no genetic or molecular biological evidence that any molecule other than fibrillin-1, or any defect other than a structural mutation, is causative of classic MFS. The mouse model of MFS has markedly altered the understanding of the pathogenesis of a growing number of the features of this condition. Microfibrils play an important role in regulating the activity of TGF- $\beta$ , and abnormal or deficient fibrillin-1 appears to lead to increased TGF- $\beta$  activity during pre- and postnatal development (19,190).

The biochemical impact of *FBN1* mutations in humans has been characterized, primarily in cultured dermal fibroblasts, by:

- (1) The size of the mutant monomer,
- (2) How much of the mutant monomer is synthesized,
- (3) How much is secreted,
- (4) How much fibrillin is deposited in the ECM, and
- (5) The ultrastructure of microfibrils (12,175,191–193).

Most mutations in *FBN1* are of the missense variety and therefore do not reduce the size of the fibrillin monomer (Figure 153-25). A dominant-negative effect seemed a plausible mechanism for addressing the fundamental question of why heterozygosity for a fibrillin mutation should be so severe, when 50% of the normal complement of monomers is being synthesized.

Initially, Dietz and colleagues provided further evidence of dominant-negative pathogenesis by transfecting normal mouse fibroblasts with a DNA construct for a human *FBN1* mutation that produces a truncated N-terminal fragment of the protein. The transfected fibroblasts showed a marked reduction of incorporation of normal mouse fibrillin into the ECM (194).

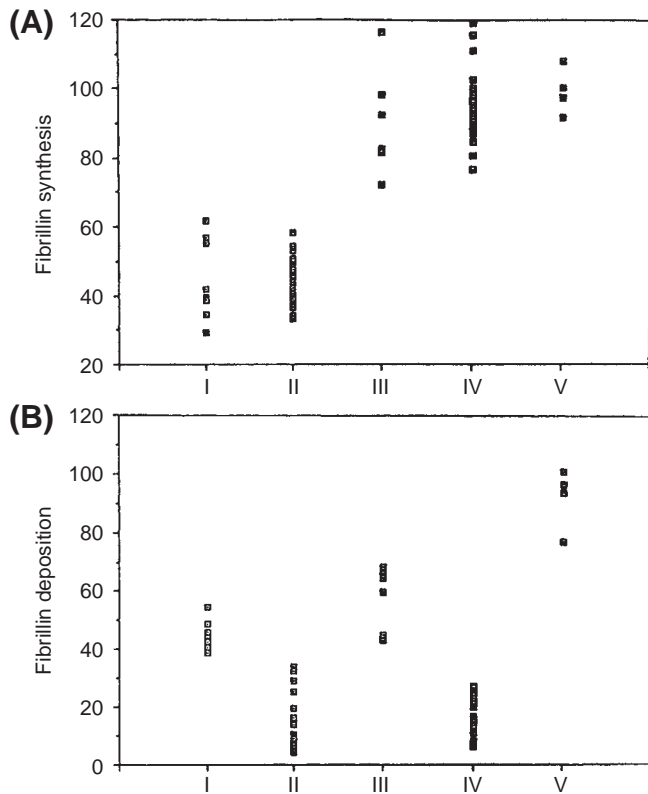

Kielty and colleagues have investigated the ultrastructure of microfibrils from patients and controls and correlated findings with biochemical characteristics. Microfibrils isolated from postconfluent fibroblast

cultures of most patients have distinct differences from control cell lines (Figure 153-26). No discernible microfibrils can be isolated from fibroblast cultures of some patients (12).

But what of the mutations that do not appreciably diminish fibrillin deposition in the ECM? One mutation results in a premature peptide chain termination; only 6% of this mutant mRNA is expressed, and the amount of mutant fibrillin-1 monomer is therefore markedly reduced. As a result, most of the monomers present are normal, the microfibrils are little affected, and the phenotype is mild. The stoichiometry of monomer interaction is apparently crucial, because premature termination mutations that produce slightly more transcript (16% and 23% mutant mRNA) are associated with a severe phenotype. By extension of these findings, a mutation resulting in a failure to produce any fibrillin from one *FBN1* allele (a null mutation) should produce an extremely mild phenotype, and this has been observed in some patients with the MASS phenotype (*vide infra*). However, a patient with no detectable mutant *FBN1* protein has severe MFS. So what constitutes a null mutation in this scheme? In searching for answers, an important consideration is the possibility that a mutant peptide or mutant mRNA might interfere with intracellular trafficking or processing of the normal monomer or mRNA. The dominant-negative effect would result in a severe phenotype, but the actual mutant product would not be detected and would be called a null phenotype. In this case, the amount of fibrillin-1 deposited in the ECM might be key to the severity (195). However, work with the mouse model of MFS, described in the next section, calls dominant-negative pathogenesis into question.

Apparently, failure to produce any normal fibrillin-1 has a major consequence on phenotype. Two parents with MFS, the father with a W217G substitution and the mother heterozygous for G2627R, produced a child who was the compound heterozygote (196). The child died of cardiac failure at age 4 months; he had previously

**FIGURE 153-26** Categorization of how mutations in *FBN1* affect synthesis and deposition of fibrillin-1 in cell culture. A, Amount of fibrillin synthesized by dermal fibroblasts, as a percentage of that synthesized by control cells. B, Amount of fibrillin incorporated into the extracellular matrix is shown. Samples in class V were indistinguishable from controls in both measures. (From Aoyama, T.; Francke, U.; Dietz, H.; Furthmayr, H. Quantitative Differences in Biosynthesis and Extracellular Deposition of Fibrillin in Cultured Fibroblast Distinguish Five Groups of Marfan Syndrome Patients and Suggest Distinct Pathogenetic Mechanisms. *J. Clin. Invest.* **1994**, 94, 130–137.)

been reported as a probable ‘homozygote’ because of the parental phenotypes and his severe features.

**153.5.8.2 Animal Models.** A model for MFS was found in nature, but unfortunately, not in the most useful of experimental animals. Potter and Besser and colleagues struggled to preserve and breed a mutation that occurred spontaneously as a germinal mosaic in a Limousin bull (197). Multiple offspring, most produced by artificial insemination, had rather classic features of MFS. Affected animals have abnormal fibrillin metabolism, but no mutation has yet been found in a gene for fibrillin, which maps to bovine chromosome 10.

Ramirez, Dietz and colleagues (198) produced two mutant strains of mice made heterozygous for mutations in *FBN1* by targeted in-frame deletions. The strain heterozygous for a mutant allele expressed at a level 5–10% of the normal allele developed only subtle skeletal changes at advanced age. The homozygotes generally died in infancy of aortic rupture. While the histopathology of the aortic lesions was similar to those in humans with MFS, the areas of disrupted elastic fibers were quite focal. This suggested that minimal expression of *FBN1* is necessary

for elastic fiber formation in the mouse aorta (198). A second mouse mutation, a targeted intron insertion, resulted in reduced expression (15%) of normal protein from the mutant allele (38). The heterozygous animal had a normal phenotype throughout life. The homozygote, however, showed both aortic and skeletal features similar to MFS. Long bones overgrew. Life expectancy was only 3–6 months, with death due to aortic rupture. Most striking was early-onset calcification of the media of all elastic arteries. The regions of calcification became more extensive with age and were associated with proliferation of vascular smooth muscle cells and inflammation of the adjacent adventitia. The advanced vascular changes were associated with expression of matrix metalloproteinases and marked elastolysis. The diffuse calcification and intimal hyperplasia were subsequently found on retrospective review of autopsy specimens of humans with MFS (27).

Mice carrying one or two copies of mutations known to cause human MFS are even better models (199,200). One strain, which carried two normal mouse alleles of fibrillin-1 and variable numbers of the aberrant human *FBN1* allele, showed no abnormal phenotype (200). In fact, these mice showed that mutant fibrillin-1 was incorporated into microfibrils. When the same ‘human’ mutation was introduced into the mouse *fbn1* locus, the MFS phenotype was produced. Introduction of the normal *FBN1* transgene onto this mutant mouse background normalized the phenotype. These results were contrary to the ‘dominant-negative’ pathogenetics mechanism, and supported haplo-insufficiency of normal fibrillin-1 as the most important determinant of the MFS phenotype.

Investigations using peptides of human fibrillin-1 carrying a mutation known to cause MFS support the notion that microfibrils are more sensitive to proteolytic degradation, by increasing the susceptibility to degradation (201), up-regulating matrix metalloproteinases (202), increasing apoptosis, or combinations thereof.

The strongest evidence for the role of altered TGF- $\beta$ -signaling (Figure 153-27) came from studies of development of the lung and the mitral valve in mice bearing MFS mutations (203). Neptune and colleagues (150) showed that there was a failure of distal alveolar septation, leading to an emphysematous-like pathology. The abnormal lung showed abnormally high levels of active TGF- $\beta$ ; treatment of perinatal MFS mice with an anti-TGF- $\beta$  antibody prevented the abnormal lung phenotype. Mice deficient in fibrillin-1 showed postnatal development of mitral valve prolapse, associated with abnormally increased TGF- $\beta$  signaling (204). As in the lung, inhibition of TGF- $\beta$  activity ‘rescued’ the Mitral valve prolapse (MVP) phenotype (Figure 153-28). Mice homozygous for a hypomorphic allele (*Fbn1*<sup>mgR/mgR</sup>) showed marked dural attenuation and elastic fiber disorganization. Increased activated TGF- $\beta$  and matrix metalloproteinase-2 was also present (67). Enhanced TGF- $\beta$  signaling through both the canonical (Smad-facilitated) and noncanonical pathways occurs (205,205a).

**FIGURE 153-27** Dominant-negative model of molecular pathogenesis of the fibrillinopathies. A, Normal synthesis, secretion, and processing of fibrillin-1 monomers leads to normal microfibrillar aggregates and a normal phenotype. B, A mutation that alters primary structure but does not interfere greatly with synthesis and secretion produces a pool of abnormal fibrillin-1 monomers that interfere with microfibrillar assembly, resulting in a severe phenotype. C, Mutations that result in either a marked reduction of transcript or a mutant peptide incapable of aggregating with the normal monomers lead to a reduced number of relatively normal microfibrils, and a mild phenotype. (From Dietz, H. C.; Pyeritz, R. E. *Molecular Genetic Approaches to Investigating Cardiovascular Disease*. Ann. Rev. Physiol. 1994, 56, 763–796, with permission.)

**FIGURE 153-28** Effect of a mutation causing Marfan syndrome of the ultrastructure of microfibrils produced by cultured dermal fibroblasts. Microfibrils from a patient with a missense mutation substituting arginine for cysteine at residue 890, in one of the two regions sharing homology for both EGF and TGF- $\beta$ 1 binding protein motifs in fibrillin-1. (Bar = 100 nm.) (From Kielty C. M., et al. (147).)

Serum from MFS mice and humans with MFS contains increased levels of circulating TGF- $\beta$  (206). Aging MFS mice develop osteopenia in association with up-regulation of Rankl in response to excess TGF- $\beta$  signaling (207).

Additional evidence for the role of excessive TGF- $\beta$  signaling in Marfan syndrome derives from the therapeutic efficacy of angiotensin receptor blockade in preventing, and even reversing, the cardiovascular phenotype in the mouse model of MFS (208). Losartan, which is in widespread use as an antihypertensive due to its antagonism of the angiotensin II type 1 receptor, also interferes with the action of TGF- $\beta$ . Prenatal treatment of mice with MFS normalizes the aortic histopathology. Additionally, and surprisingly, MFS mice who are not treated until 2 months of age (adolescence in human terms) have little aortic or lung pathology when sacrificed at 8 months of age. Mice lacking signaling through the angiotensin II type 2 receptor have accelerated aortic disease, and signaling through the type 2 receptor is required for the protective effect of losartan. Losartan, as opposed to angiotensin converting enzyme inhibition, blocked enhanced signaling through the ERK pathway (noncanonical pathway) (208a). Treatment of MFS mice with losartan does not improve osteopenia, but treatment with the bisphosphonate, alendronate, does (207). Human trials of angiotensin receptor blockade are in progress (209).

Mice carrying one copy of the tight skin (*Tsk*) mutation, which occurred spontaneously, have thickened skin firmly adherent to underlying tissue, excessive accumulation of collagen and glycosaminoglycan in many tissues, increased size due to overgrowth of cartilage and bone, and normal life span (210). The *Tsk/Tsk* genotype results in embryonic lethality. The mutation was mapped to chromosome 2, in a region syntenic with human chromosome 15q21. This prompted examination of the mouse fibrillin-1 locus, which was shown to harbor a large genomic duplication (211). The mutation causes a 14-kb, as opposed to the normal 11-kb, transcript. The molecular pathogenesis remains unclear. Of interest is the development in *Tsk/+* mice of autoantibodies to fibrillin-1. Humans with scleroderma also develop antibodies to fibrillin-1 (212). Furthermore, scleroderma is especially common in the Choctaw Native Americans, and a candidate gene-association study showed linkage between the disease and polymorphic markers near *FBN1* (213).

### 153.5.9 Diagnosis

Each of the clinical features of MFS occurs with variable frequency in the general population. Occasionally, several will occur together by chance alone. In determining which of these individuals are affected by MFS, some other systemic connective tissue disorder, or no clear syndrome, more diagnostic reliance is placed on the presence of manifestations that are at once uncommon in the population but common in MFS (subluxed lenses, aortic dilation or dissection, dural ectasia) than on soft features (myopia,

**TABLE 153-4 Diagnostic Criteria for Marfan Syndrome: Revised Ghent Criteria**

In the absence of a family history	
Marfan syndrome is present if:	
[1] The aorta is dilated ( $Z \geq 2.0$ ) and ectopia lentis is present;	
[2] The aorta is dilated and a mutation in <i>FBN1</i> known to cause MFS is present;	
[3] The aorta is dilated and the systemic score* totals 7 points or more <sup>a</sup> ; or	
[4] Ectopia lentis and a mutation in <i>FBN1</i> known to be associated with a dilated aorta are present.	
In the presence of a family history	
Marfan syndrome is present if:	
[5] Ectopia lentis is present;	
[6] The systemic score* totals 7 points or more; or	
[7] The aorta is dilated ( $Z \geq 2.0$ if 20 years old or older; $Z \geq 3.0$ less than 20 years).

mitral prolapse, tall stature, joint laxity, and arachnodactyly). The clinical diagnostic criteria last proposed (2010) by an international committee (57) and referred to as the ‘Revised Ghent Criteria’ are summarized in Table 153-4. These criteria make it less likely that, for example, the familial occurrence of scoliosis, pectus excavatum, and mitral valve prolapse, while meriting consideration of MFS, warrants that diagnosis (214), and more likely that these features may well represent the MASS phenotype (94). In comparison with the original Ghent criteria (215), more emphasis is placed on aortic dilatation, ectopia lentis and a mutation in *FBN1*. Less emphasis is placed on dural ectasia, mainly because a separate radiological imaging study is necessary to detect it. The major weakness of

the new criteria is the reliance on the ‘Z-score’ to define aortic dilatation, with a score of  $>+2.0$  being required; this represents a measurement greater than two standard deviations above the mean adjusted for age, sex and body surface area. Without any change in the aortic diameter, the interpretation of whether it is dilated or not in the same patient can vary as the patient grows, or gains or loses weight. Thus there is the possibility that the diagnosis of MFS can vary for purely trivial reasons. Additionally, very large individuals can have an aortic Z-score less than 2 despite the actual diameter being larger than 40 mm, which is considered pathologically dilated in the minds of most cardiologists (216).

Two specialized studies are required of any person in whom MFS is suspected: slit-lamp examination of the eyes and echocardiography. The former establishes whether ectopia lentis is present. Echocardiography is needed to determine whether MVP and aortic root dilation are present.

Conditions that must be excluded when considering the diagnosis of MFS include homocystinuria, contractural arachnodactyly, a number of the Ehlers–Danlos variants, and familial mitral valve prolapse or MASS phenotype. A variety of other conditions include one or more of the clinical features of MFS but would rarely be confused; these are listed in Table 153-5. The ‘marfanoid hypermobility syndrome’ (OMIM 154750) and the ‘neonatal MFS’ (217) are not separate entities; rather they represent exceptional variants of the classic phenotype.

Homocystinuria (see Chapter 92) must be excluded in any patient thought to have MFS because the pleiotropic manifestations of the two conditions include many of the same organ systems. Homocystinuria is ruled out effectively by a negative quantitative amino acid analysis of plasma (218). Patients with the pyridoxine-responsive form of homocystinuria may have a mild phenotype and escape detection until adolescence or adulthood, especially if they unwittingly take regular multivitamin supplements containing folate and B<sub>6</sub> (219). Such cystathionine  $\beta$ -synthase-deficient patients may have a negative qualitative urine screen for disulfides.

Congenital contractural arachnodactyly (CCA) is an autosomal dominant condition characterized by features recognizable at birth, including contractures of the digits, elbows, and knees; folding or ‘crumpling’ of the superior helix of the ear; and arachnodactyly (51). This condition is much less common than MFS. Some patients who clearly have MFS also have congenital contractures and abnormal ears. Thus any patient suspected of having CCA should have echocardiography and detailed ophthalmological examination. The joint contractures in CCA usually respond well to physical therapy begun early in life. Considerable risk of developing scoliosis requires persistent attention during childhood and adolescence in any person with CCA (220). Linkage of CCA to the *FBN2* locus has been clearly established (20), and point mutations occur in the EGF-like and TGF $\beta$ <sub>1</sub>-BP-like motifs of this gene (221).

**TABLE 153-5 Other Conditions Sharing Clinical Features with Marfan Syndrome**

Relapsing polychondritis
Ankylosing spondylitis
Reiter syndrome
<i>Skin</i>
MASS phenotype
<i>Dural ectasia</i>
Neurofibromatosis, type I
Lateral meningocele syndrome (387)

Patients with Ehlers–Danlos syndrome of the classic or hypermobility types (previously termed types I, II, or III) may be asthenic and have skeletal deformity (see Chapter 154). Mitral valve prolapse occurs frequently, and occasionally the aortic root may dilate somewhat (222). Generally, the body proportions are not disturbed, as in MFS. Severe joint laxity and skin hyperelasticity argue against MFS.

Persons with the MASS phenotype may have mitral valve prolapse, scoliosis, thoracic lordosis, asthenia, striae, and pectus excavatum, but they lack lens subluxation or severe aortic involvement. These features are heritable as an autosomal dominant trait (94).

The first steps in establishing the diagnosis should always be a careful medical history, family history and physical examination. Determination or rejection of the diagnosis of MFS on purely clinical grounds often must await the results of the detailed ophthalmological examination and echocardiogram. Understanding the molecular basis of MFS has greatly aided diagnosis in specific instances (166), but *FBN1* mutations cause conditions other than MFS, often the very conditions that clinicians are interested in excluding (Table 153-6).

Diagnosis by linkage analysis is rarely necessary today. Similarly, immunofluorescence assays of fibrillin incorporation into the ECM of cultured fibroblasts – so important in pointing to the cause of MFS (164) – have no value in diagnosis of patients with equivocal clinical findings.

Prenatal diagnosis is possible by mutation detection using DNA from amniocytes or chorionic villi (223). Mutation detection using DNA from single cells removed from preimplantation blastocysts is also feasible (194), and is being clinically applied (224,225).

### 153.5.10 Management

No specific therapy exists for the underlying defect in MFS. Therapeutic efforts are directed at first establishing an accurate diagnosis, determining which problems are present at diagnosis, anticipating the problems that will probably arise in the future, and pursuing certain prophylactic measures for specific problems. These patients should have one physician who is knowledgeable about the syndrome, who serves as the primary caregiver, and who refers to specialists as the need arises. One approach for guiding the overall management is an ‘integrated care pathway’ (226). While this approach may help the primary care physician who is unfamiliar with MFS, and does reduce inter-practice variation, no formal assessment of effectiveness has been performed.

Encouraging and facilitating adolescents with MFS to transition to self-management is a crucial aspect of long-term care (227–229).

**153.5.10.1 Skeletal.** All children with any evidence of scoliosis and all adults with a progressive deformity should be evaluated by an orthopedic specialist regularly, perhaps semiannually. Scoliosis of greater than 10° in children should be pursued aggressively if the curve progresses, with physical therapy and mechanical bracing. Bracing is not beneficial for curves greater than 40–50° and is unlikely to be effective for scoliosis of the thoracic spine in the face of concomitant thoracic lordosis (230). Spinal surgery is necessary when bracing fails to halt progression and in curves of greater than about 40° (64,230,231). In the past, spinal surgery in children stunted further growth of the segments of the vertebral column instrumented, and resulted in excessive trunk disproportion. Extensible spinal growing rods mitigate this problem (232). Issues to address in advance of surgical correction include the patient’s cardiopulmonary

<sup>a</sup>This mutation also causes classic Marfan syndrome.

status, the adequacy of the bone to withstand fixation, and the presence of dural ectasia (66,233).

Scoliosis tends to progress most during rapid growth, especially in early adolescence. If this adolescent growth spurt can be shortened, the scoliosis may not progress so far. A second benefit of decreasing the length of time that the bones have to elongate is a reduction in adult body height. Girls can be treated before menarche with estrogen on a daily basis, to induce puberty and epiphyseal closure. Progestagen is added for five days each cycle to prevent dysfunctional bleeding. Alternative schemes for hormonal therapy also work. No conclusive data are yet available to show whether scoliosis is abated by this approach. Adult height has clearly been reduced in women who begin therapy before the menarche (234) (Figure 153-29).

Other orthopedic problems associated with joint instability should be managed by an orthopedic surgeon familiar with connective tissue disorders. The major indication for repair of anterior chest deformity is cardiopulmonary compromise, and repair should be deferred until late adolescence if possible (235). Repair early in life provides many years for rib growth to depress the sternum and re-establish the deformity. The so-called minimally invasive technique for repair of pectus excavatum has not been formally studied in MFS (236).

Even though many people with MFS complain of pain in the feet, few need aggressive therapy (237). Finding shoes to fit the long, narrow feet properly is a difficult and expensive chore, but one well worth the effort.

**153.5.10.2 Ocular.** The patient should be evaluated annually by an ophthalmologist experienced in connective tissue disorders. Emphasis should fall on correction of refractive errors and management of amblyopia; documentation of the direction and degree of lens subluxation; and detection of anterior chamber abnormalities, cataracts, glaucoma, and retinal detachment. Greater than 90% of patients can be refracted to vision better than 20/40 without lens surgery. Full correction should be pursued as early as possible and amblyopia treated aggressively.

All patients and their families should be counseled about the earliest symptoms of retinal detachment and the necessity of seeking evaluation immediately. Advances in the techniques of intraocular surgery have markedly improved the risk of postoperative retinal detachment to less than 5%, even in children (238,239). Similarly, the chances of a successful operative repair for retinal detachment have improved (240). The subluxed lens usually does not require surgery, except when adequate correction of the refractive error is impossible because of complex refractive errors, or because of phacodonesis, cataracts, phacolytic glaucoma or impending total lens dislocation (81). When the displaced lens is left in situ, optical correction can be achieved through the lens (phacically) or around the lens (aphakically). An aphakic correction can be facilitated by chronic use of atropine eye drops. Optical correction can be achieved through the use of glasses, contact lenses, or both. When the lens is removed, implantation of an artificial lens is a reasonable alternative. An artificial lens should not be implanted into the anterior chamber because of the high risk of endothelial cell loss secondary to excess lens mobility due to disparity in size.

Several approaches to surgical correction of myopia have appeared over the past decade. All involve sculpting the cornea to make it flatter, thereby counteracting the effects of the lens and the increased length of the globe. Typically in MFS, the cornea is already abnormally flattened (but not thin). The progressive nature of lens dislocation may prevent achieving long-term adequate correction. Thus corrective corneal surgery should not be performed in children. The adult patient desiring corneal surgery for myopia should be counseled by an ophthalmic surgeon well versed both in MFS and the techniques available; the diagnosis of MFS may be a contraindication.

**153.5.10.3 Cardiovascular. Routine Evaluation.** The frequency of cardiological evaluation depends on the severity of the manifestation. If the patient has only mitral valve prolapse and a mildly dilated aorta without any valvular regurgitation, an annual examination including

**FIGURE 153-29** Schematic interaction between TGF- $\beta$  and fibrillins. (From Kaartinen, V. & Warburton, D. (384), with permission.)

an echocardiogram is sufficient. As the aorta dilates and as valvular regurgitation appears and progresses, more frequent examinations are indicated. A periodic ECG is warranted for patients with known dysrhythmia, coronary artery disease, or ventricular dysfunction. Children, adolescents, and young adults with classic MFS and no dissection are very unlikely to have dilation elsewhere in their vasculature other than the aortic root, so routine angiography by CT or MR is not warranted.

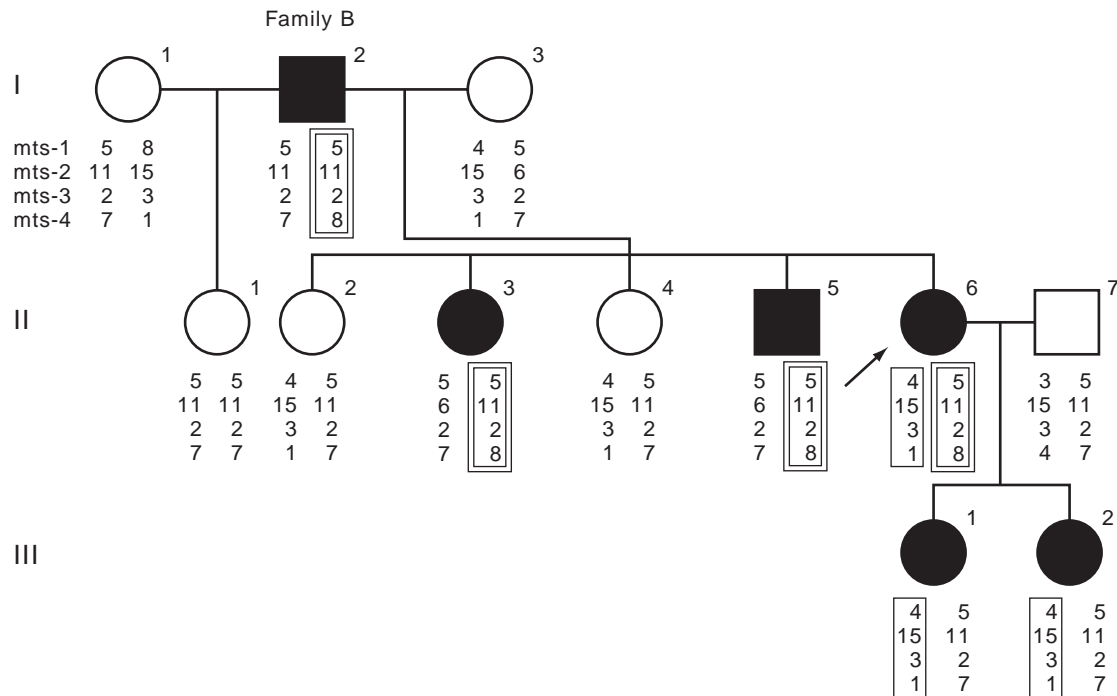

**Activity Modulation.** The dilated aorta is susceptible to rupture or dissection, either spontaneously or following modest trauma. The shearing forces of ventricular ejection may be the driving forces behind dissection and dilation. For these reasons, some restriction of patient activity seems warranted (241). Patients should not engage in contact sports, activities requiring maximal exertion, or isometric exercise. Most prepubertal children do not require stringent restrictions. However, their interests and activities should be channeled away from competitive athletics.

**$\beta$ -Adrenergic Blockade.** The use of  $\beta$ -adrenergic blockade to delay or prevent severe aortic complications was suggested four decades ago (242,243), but convincing evidence of its utility appeared much later (244–246). In a prospective randomized trial of propranolol in patients with mild to moderate aortic dilation, two beneficial effects of chronic  $\beta$ -blockade occurred: the rate of aortic root enlargement was lessened (Figure 153-30) and fewer patients developed aortic regurgitation or dissection during the course of the study (246) (Figure 153-31). Any patient with classic MFS should be considered for prophylactic therapy. Atenolol is the drug we currently use first; it is relatively cardioselective, is less lipophilic (so central nervous system side effects are minimal), and has a longer half-life than propranolol. In adults, we begin treatment at 50mg in the

(150) Copyright Nature Publishing Group, with permission.)

morning and advance the dose (giving an evening dose as the next step), to keep the resting heart rate at less than 60beats/min and the heart rate during moderate

**FIGURE 153-31** Pedigree in which both classic Marfan syndrome and a milder connective tissue disorder segregate. Individuals II-6, III-1, and III-2 have Marfan syndrome, linked to *FBN1* (haplotypes of polymorphic markers shown below pedigree symbols). Individuals I-2, II-3, and II-5 have not inherited or passed on the same *FBN1* allele that occurs in Marfan relatives, but have mild skeletal and cardiovascular features that suggested Marfan syndrome to their physicians. Whether these individuals also have a mutation in *FBN1* or another component of the ECM is still under investigation. (From Pereira, L.; Levrin, O.; Rameriz, F., et al. *Diagnosis of Marfan Syndrome: A Molecular Approach for Stratification of Cardiovascular Risk within Families*. N. Engl. J. Med. **1994**, 331, 148–153.)

exercise at less than 100beats/min. Because of marked variation in individual responsiveness to all  $\beta$ -adrenergic blocking agents, the dose must be titrated for patients of any age. We begin treatment in children as soon as possible. As noted above, circulating levels of TGF- $\beta$  are increased in people with MFS. Chronic treatment with a  $\beta$ -blocker (or an angiotensin receptor blocker) reduces the serum level of TGF- $\beta$  (206).

Chronic treatment with  $\beta$ -adrenergic blockade reduces left ventricular inotropy, which in turn reduces  $dP/dt$  in the aorta (247). In addition, we and others (96,248) have shown that chronic  $\beta$ -adrenergic blockade tends to normalize the compliance of the aortic root in people with MFS. Presumably this response is beneficial, but this notion has not been tested in long-term follow-up. Moreover, the improvement in stiffness is not uniform in all patients (248), and patients with less aortic root dilation may respond best (249,250).

The adverse effects of long-term therapy with  $\beta$ -adrenergic blockers must be considered and potentially monitored. Serum high-density lipoprotein levels are reduced slightly. There is an increased risk of developing type 2 diabetes mellitus, although the risk is small, it can be monitored, and it has been documented only in patients taking  $\beta$ -blockers because of hypertension. People with MFS often complain of fatigue and diminished libido (160); the contribution of medications to these symptoms is unclear.

**Other Medical Therapy.** Not all people tolerate  $\beta$ -adrenergic blockade. Whether alternative medications have salutary effects on the aortic root remains an open question. In the past, we and others used verapamil, a calcium channel blocker of the non-dihydropyridine class, with modest negative inotropic activity, as a first alternative to  $\beta$ -blockade. Recently, utilizing mouse models of MFS, Dietz and colleagues demonstrated convincingly that treatment from early in life with any of the classes of calcium channel blocker greatly accelerated aortopathy [Dietz HC. Personal communication]. A study is currently underway to investigate this issue retrospectively in humans. Until that study produces results, it would be prudent to avoid calcium channel blockers in MFS for any reason.

Losartan, an angiotensin receptor blocker (ARB), has several additional effects that reduce local effects of TGF- $\beta$ . Because of the evidence of excess TGF- $\beta$  activity in the pathogenesis of MFS, losartan was given to neonatal Marfan mice, with beneficial reduction in aortic medial pathology (208). When therapy with losartan was delayed until the MFS mice were 2 months old (adolescence to a mouse), the already dilated aorta reverted to normal caliber and histopathology. Dietz and colleagues treated 18 severely affected young MFS patients with an ARB. These patients were on optimal doses of  $\beta$ -adrenergic blockade, but had progressive dilatation of their aortic roots. Treatment with an ARB

(losartan in 17 instances) resulted in stabilization of dilatation in all cases (251). These results have stimulated half a dozen human trials of ARBs of various designs around the world (252). The largest and most advanced is supported by the National Heart, Lung and Blood Institute and completed recruitment of subjects in early 2011. Young subjects with considerable dilatation of the aortic root were randomly assigned to take atenolol or losartan for 3 years (209). Until the results of this and other clinical trials of ARBs in humans with MFS are completed, caution should be used before recommending this class of drug as an alternative to  $\beta$ -adrenergic blockade.

**Cardiovascular Surgery.** The proximal aorta was recognized as being at risk for dilation and dissection in MFS in 1943. Disease of the aorta was documented as a major problem in 1955, and as the leading cause of death in MFS by far in 1972. Until relatively recently, however, no reliable surgical approach to correcting aortic pathology was available. The first attempts to repair the aortic root in any condition were not reported until 1964. When applied to MFS, both short-term (operative) and, for the fortunate few who left the hospital, long-term results were discouraging. The aneurysmal tissue was difficult to repair, all of the sinus of Valsalva could not be resected, and the tissue was friable. A major advance occurred in 1968 with the report of Mr. Hugh Bentall, a surgeon in London (253). He devised the ‘composite graft’, in which a prosthetic aortic valve is sutured into one end of a Dacron conduit; this permitted resection of the entire aortic root aneurysm and aortic valve, with suturing to the tough aortic annulus and the distal ascending aorta. While nearly a decade was required for this technique to be widely applied in MFS in the United States and Europe, the short-term results were so encouraging that no controlled trial evaluating different techniques was ever performed (Figure 153-32).

Surgical correction of the proximal aorta and aortic valve is required in several situations: in an acute emergency due to rupture, dissection, or severe left ventricular decompensation; when early signs of left ventricular strain appear in the presence of severe regurgitation; and for enlargement of the aortic root even if the aortic regurgitation is mild or absent. Use of the composite graft (Figure 153-33) resulted in a dramatic decrease in perioperative mortality of aortic surgery in MFS (254,255). Through early 2011, none of more than 350 patients who underwent elective repair of the aortic root for MFS at the Johns Hopkins Hospital failed to leave the hospital (D. Cameron, personal communication). A prosthetic valve requires lifetime anticoagulation. In young children and for those with a strong contraindication to coumarin derivatives, the use of a fixed homograft (aortic valve and proximal aorta, from a human cadaver) works well; the major concern is loss of pliability of the aortic cusps with time. Pulmonary autografts (the so-called Ross

**FIGURE 153-32** Hormonal modulation of height in girls affected by Marfan syndrome. In all cases, treatment with ethinyl estradiol (0.05 mg/10 kg/day) and conjugated estrogen (Premarin, 10 mg, days 25–28, each menstrual cycle) was begun before menarche. Therapy was continued until the time menarche was likely to have occurred naturally or until bone maturation was well advanced, whichever occurred first. Comparison with Figure 153-6B shows early cessation of growth and reduction in height of the treated girls.

procedure) (256) are not recommended because the main pulmonary artery contains the same medial degeneration as does the dilated aortic root.

Beginning in 1983 with the work of Sir Magdi Yacoub in London and greatly advanced by Dr. Tirone David in Toronto, various techniques to preserve the native aortic valve while replacing the dilated sinuses of Valsalva and proximal ascending aorta have emerged (257–259). Results of valve-sparing employing the ‘reimplantation’ approach have been quite encouraging (258,260–264). The notion of preserving the aortic valve is appealing for anyone faced with lifelong anticoagulation, but particularly so for young women who wish to attempt pregnancy and for anyone with a relative contraindication to warfarin. However, no randomized trial has been performed (and would be difficult in any event), and even comparing the results among centers and surgeons is difficult because of different techniques and indications. However, a registry of aortic surgical results was established by the National Marfan Foundation in the USA; analysis of the intermediate-term results of several hundred patients found that root repair by the reimplantation technique (David V approach) was an excellent alternative to the composite graft (265). The best candidates

are those with no or minimal aortic regurgitation and an aortic root dimension of 45–55 mm. If a patient has a family history of aortic dissection, the criterion for prophylactic repair should be 50 mm or lower. For children, two criteria are useful: when the aortic root dimension exceeds twice that predicted for the age and body surface area (93,95) or twice the diameter of the distal ascending aorta or proximal descending aorta. Reimplantation remodeling is effective in children with MFS (266).

Occurrence of aortic dissection before repair of the aortic root, whether the initial dissection involved the entire aorta (type A) or just the descending portion (type B), decreases life expectancy (255,267). The reduced life expectancy is due to multiple factors, including the morbidity and mortality of further dissection and that of subsequent aortic surgery. On a positive note, the techniques for repairing extensive dissections involving the aortic arch, which involve deep hypothermic total circulatory arrest (268,269), and the abdominal aorta (270) have greatly improved. In a number of instances, patients have had the entire aorta replaced by prosthetic material (271). Recently, endovascular stents have been used in abdominal aortic aneurysms (AAA) and thoracic dissections due to inflammatory and atherosclerotic disease (272). While such an approach is of potential benefit because of the avoidance of major surgery, its use in MFS is not to be recommended at this time, despite rare reports of short-term success (273).

Some patients require mitral valve surgery alone, or in addition to aortic surgery. In most cases, repair rather than replacement of the mitral valve is possible, with acceptable long-term outcome (274,275).

After any repair of the aorta, patients should be maintained on chronic  $\beta$ -adrenergic blockade. Additional medications should be employed aggressively to control blood pressure in the normal or low-normal range. As noted above, calcium channel blockers may have long-term deleterious effects, although this needs to be documented in humans. Likewise, a disturbing number of MFS patients who had prophylactic root repair and were treated post-operatively with an ARB have subsequently developed acute dissection of the descending thoracic aorta (type B) (Craig Miller & David Liang, personal communication). This anecdote requires confirmation, but brings into question what additional medications might be employed. An inhibitor of angiotensin-converting enzyme might be the next choice.

Function of the prosthetic aortic valve and the left ventricle should be monitored by echocardiography at least annually. The entire aorta should be examined by CT or magnetic resonance angiography before surgery (276). If no occult dissection or dilation beyond the root is present, examination every 2 years is warranted. In one study, 43% of patients who had had prophylactic aortic root repair developed some degree of dilation of one or both coronary ostia (277); these tended not to progress, but exceptions are reported (278). The risk is

lower when the ostia are reimplanted with the button technique rather than the original Bental wrap approach (279). Following aortic root repair, the rate of dissection of the distal ascending aorta is low, so that routine, concomitant replacement of the transverse arch may not be warranted (280). Complications requiring reoperation are higher in any patient who had a type A dissection at the time of initial repair (255,281).

Only a small number of persons with MFS have undergone cardiac transplantation; survival was about 50% after nearly 3 years (282).

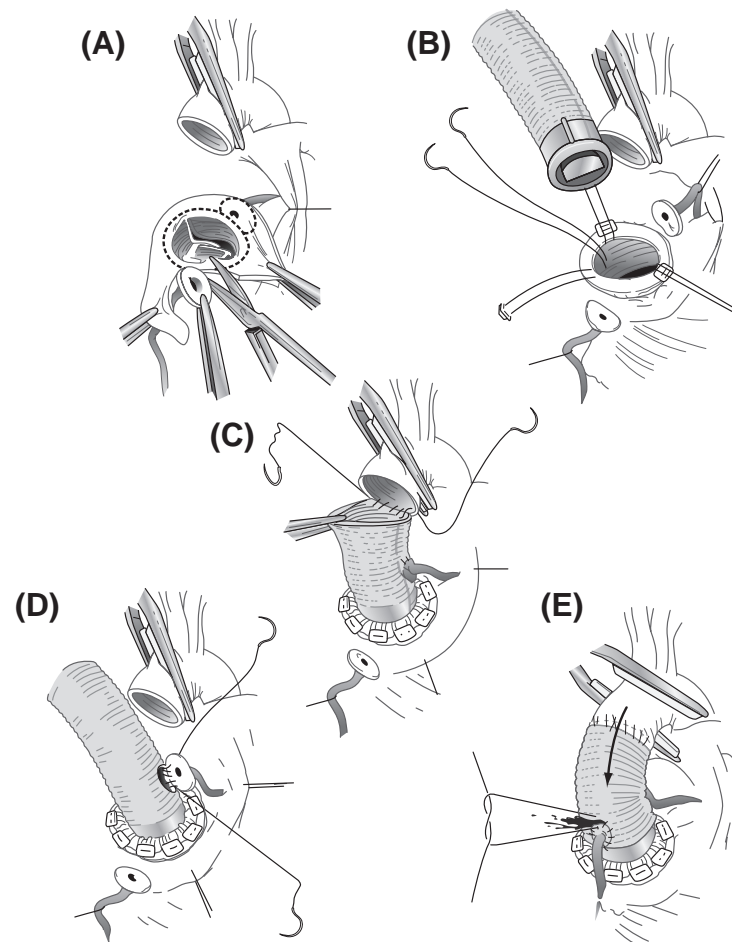

**Endocarditis Prophylaxis.** All persons with MFS are potentially at increased risk of endocarditis because of the abnormal ECM of the cardiac valves, regardless of whether demonstrable valvular abnormalities exist. However, at this time only patients with mild or worse valvular dysfunction should be instructed to practice routine (oral) antibiotic prophylaxis at the time of dental, genitourinary, and selected other procedures (257). Patients who have undergone uncomplicated composite graft repair or valve-sparing surgery may not be at any more risk for endocarditis than preoperatively. More aggressive prophylaxis involves parenteral antibiotics, such as injected ampicillin plus gentamicin; for those allergic to penicillins, vancomycin can be substituted.

**Pregnancy.** In the general population, most dissection of the aorta in young people occurs in pregnant women; all the factors are not certain, but hormonal changes, increased blood volume, increased cardiac output, and the sudden volume surge of autotransfusion as the uterus contracts postpartum probably contribute. All women with MFS are at further increased risk of aortic dissection during pregnancy, especially if the aortic root dimension is greater than 40 mm (114). However, most women with MFS suffer no major complication (*vide supra*) (112,114,116,283). What criteria might define women at the highest risk? We suggest the issues listed in Table 153-7 be explored in any woman with MFS of childbearing age. We perform echocardiography and cardiovascular assessment every 6–8 weeks during pregnancy.

Whether to keep a pregnant woman on  $\beta$ -adrenergic blockade as she attempts to conceive and during pregnancy is not settled (79). My personal preference is not to expose the early fetus to medication unless a strong reason, such as supraventricular tachydysrhythmia, occurs.  $\beta$ -Blockade can be instituted during the second half of gestation, with virtually no teratogenic risk. At delivery, the effects of fetal bradycardia and hypoglycemia can be managed by the neonatologist.

Although clinical series have arrived at different conclusions, cervical incompetence occurs with an increased frequency in women with MFS, and this, in large part, accounts for the reports of spontaneous fetal loss and preterm delivery (114).

Delivery should be by whatever approaches to anesthesia, volume support, and parturition are least hemodynamically stressful to mother. Cesarean section is

**FIGURE 153-33** Technique of composite graft repair of the aortic root. A, Button of aortic wall surrounding each coronary ostium is trimmed. B, Composite graft is sutured to the aortic annulus after excision of the native aortic valve. C, Distal anastomosis is constructed to the ascending aorta proximal to the innominate artery. D, The coronary ostial buttons are next sutured to holes cut in the woven Dacron of the conduit. E, The aortic clamp is released, permitting retrograde flow of blood, and air is evacuated from the graft. The patient can then be weaned from cardiopulmonary bypass. (From Coselli, J. S.; Crawford, E. S. *Composite Aortic Valve Replacement and Graft Replacement of the Ascending Aorta Plus Coronary Ostial Reimplantation*. Semin. Thorac. Cardiovasc. Surg. 1993, 5, 55–62, with permission.)

not indicated for other than standard obstetric reasons. Excessive postpartum hemorrhage associated with uterine inversion can occur (115).

**153.5.10.4 Pulmonary System.** Because of the risk of pneumothorax, people with MFS should be counseled to avoid rapid changes in atmospheric pressure such as occur during scuba diving and flying in unpressurized aircraft. Management of pneumothorax follows standard guidelines (284) with the caveat that recurrence is highly likely and more aggressive initial therapy should be considered. Because MFS predisposes to developmental anomalies of the lung that resemble emphysema, all patients should be counseled even more rigorously than is typical against smoking. The potential for atlantoaxial rotatory instability should be considered during tracheal intubation and positioning for surgery (69); however, this is more of a problem for patients with Loeys–Dietz syndrome (285).

**153.5.10.5 The Dura.** Dural ectasia can cause radicular pain in the buttocks and legs; nerve root paralysis affecting bowel and bladder function and motor

function in the legs; and dull, unremitting discomfort in the lower abdomen and pelvis. In a woman with the latter complaints, pelvic ultrasound may show a cystic mass that is interpreted as an ovarian cyst. Gynecological surgery should never be performed in a woman with

MFS before considering the presence of anterior meningoceles. A variety of treatments have been attempted for symptomatic dural ectasia, and none is consistently effective. Pain relief can be obtained sometimes by non-traditional analgesics, such as antidepressants and antiepileptics. Surgical placement of shunts draining CSF into the peritoneum can decompress meningoceles and reduce stress on nerve roots. Rarely can the neural sacs be tied off or resected because of the nerve roots that track over the dura. Medications that reduce CSF pressure, such as acetazolamide, have not been subjected to clinical trial.

### 153.5.11 Counseling

One major issue in genetic counseling is straightforward, each affected person having a 50% probability of passing the allele to any offspring. When MFS is diagnosed in a young child and the family history is negative, the parents must be carefully examined to ensure that neither has signs of MFS. If both parents are phenotypically normal, considerable reassurance can be given that the risk of future affected offspring is slight (see discussion of germinal mosaicism, *vide supra*).

Women affected with MFS must deal with two concerns. The first is the 50% risk that any offspring will inherit the syndrome. The second concerns the risk of cardiovascular problems during pregnancy. Parents should be counseled about the range of intrafamilial variability in MFS. Affected offspring may be more or less severely involved than their parents.

The complex issues in transitioning responsibility of care from parent to affected child should be addressed longitudinally over a period of years (227–229).

**FIGURE 153-34** Effectiveness of chronic propranolol therapy in reducing cardiovascular events in Marfan syndrome. Subjects were followed until the study was terminated by death, developing aortic regurgitation, or dissection, or need for aortic surgery.  $\beta$ -Adrenergic blockade was associated with consistent protection, especially in the middle years of the trial.

Genetic counseling sessions are also an opportunity to address a person's perception of MFS – its seriousness and effects on lifestyle, occupation, and psyche. Patients have to grapple with the prospects of lifelong medication and modulation of exercise and lifestyle (286–288). One study found compliance with recommendations about medication and activity approached 80% and began to identify issues associated with noncompliance (160,287). Patients may be more willing to discuss compliance with medication and adverse effects of medication with a counselor (250).

Support groups for MFS have been established in many countries. The National Marfan Foundation in the United States maintains web-based resources (<http://www.marfan.org>), and sponsors national meetings for patients and families and periodic international gatherings of investigators. The International Federation of Marfan Syndrome Organizations (<http://marfanworld.org>) also exists.

### 153.5.12 Life Expectancy

Compared to the natural history study of nearly three decades ago (59,168), an examination of contemporary clinical history shows a marked improvement of about 25% in life expectancy for men and women (288–290) (Figure 153-34). This gain is due primarily to both better survival after cardiovascular surgery and early, prophylactic surgical intervention (255). Viewed another way, over the past 30 years, life expectancy has increased by about 30 years (291).

## 153.6 DISORDERS RELATED TO MARFAN SYNDROME THROUGH PHENOTYPE, ETIOLOGY OR PATHOGENESIS

### 153.6.1 MASS Phenotype (OMIM \*157700)

Concern about the possible diagnosis of MFS is a common reason for referral to medical genetics clinics (292). Many such probands have one or more features of MFS but fail to meet strict criteria (see Table 153-4). We conducted a systematic examination of such referrals to one clinic and found that many patients have clear evidence of a systemic disorder of connective tissue that merges with the mild end of the Marfan phenotypic spectrum (94). The acronym MASS represents common (but not essential) involvement of the mitral valve, the aorta, the skin and the skeleton.

MVP as an echocardiographic entity occurs in perhaps 2.5% of the general population (293), is more common among women, and is more common in adolescence and young adulthood than in childhood or old age. MVP is an autosomal dominant trait in many families. Based on standard transthoracic echocardiographic evaluation, two classes of MVP can be defined: those with abnormal

leaflet motion but normal leaflet morphology; and those with both prolapse and thickening of the leaflets, which correlates with the degree of myxomatous degeneration (294). The latter is sometimes termed **primary MVP**; is typical of the MVP in most heritable disorders of connective tissue, including MASS phenotype; and is more likely to be associated with clinical complications. In some people, MVP is associated with deformity of the chest wall or the vertebral column, or both. In our study, patients also often had an aortic root dimension near the upper limit of normal for age and body surface area (but no dissection or apparent progressive enlargement), myopia (but by definition no ectopia lentis), joint hypermobility (in addition to pectus excavatum and scoliosis), and striae atrophicae. Although inheritance was not specifically explored, some probands had a family history of similarly affected relatives. Subsequently, pneumothorax has been seen in a number of patients. Thus, the MASS phenotype is not MFS, although in some instances it certainly resembles what one would expect a mild variant of MFS to be. The MASS phenotype seemingly has a good prognosis, with the worst manifestation being a predisposition to progressive MVP and mitral regurgitation. Whether and how ‘familial MVP’ and MASS phenotype should be distinguished have not been clarified (183).

The MASS phenotype is likely heterogeneous in etiology, hence the term **phenotype**, rather than syndrome. A very few patients with a mutation in *FBN1* qualify for a MASS phenotype diagnosis (187,195). One example is a patient with a mutation that results in little abnormal fibrillin monomer and is close to a null allele. In general, mutations near the 3'-terminus of *FBN1*, little expression of the mutant allele, and in vitro deposition of fibrillin in the ECM greater than 70% of normal are all associated with a milder MFS-like phenotype (183,187,195). However, other patients with missense mutations near the 3' end of *FBN1* have had a severe, classic MFS phenotype. Meanwhile, other pedigrees that could be characterized as MASS are not linked to *FBN1* (295,296). Moreover, three loci for familial MVP have been mapped, Xq28, 13q31.3–q32.1, and 16p11.2–p12.1 (297–299). Finally, a family with MVP inherited as an autosomal dominant trait showed linkage to 10q32 (Yuan, unpublished). Some of the relatives, including a few with documented MVP, developed idiopathic dilated cardiomyopathy; a previous family with autosomal dominant cardiomyopathy had been mapped to the same locus (300).

### 153.6.2 Ectopia Lentis (OMIM \*129600)

Pedigrees with autosomal dominant ‘isolated’ ectopia lentis without deformity of the pupil have been described for many years. Pleiotropic manifestations suggestive of a systemic connective tissue disorder were not noted. In addition, ectopia lentis exists as an autosomal recessive trait without signs of a systemic connective tissue disorder (OMIM 225100) (301). Recently, however, attention

has been redirected to identifying families and to determining etiology because of the discovery of *FBN1* mutations in MFS. Linkage to *FBN1* was found (20,302) and mutations reported (303–306). Interestingly, most of the families reported with mutations in *FBN1* come close to qualifying for the Marfan diagnosis, in that relatives with ectopia lentis have tall stature, scoliosis, joint laxity, or pectus deformity. In several families, a mutation in *FBN1*, R240C, was found associated with ectopia lentis (307), while the same mutation was found in a family with classic MFS (308). Faivre and colleagues examined 146 adults who did not meet diagnostic criteria for MFS (using the old Ghent criteria) but who had an apparently pathological mutation in *FBN1* (309). Of those whose only major manifestation of MFS was ectopia lentis, most had missense mutations involving cysteine, none were truncating, and few occurred in the middle exons of the gene. This latter study emphasizes that at least some families ascertained through ectopia lentis should be followed for the possible development of cardiovascular features.

Mutations in *ADAMTSL4*, which encodes a metalloproteinase, occur in a consanguineous family with recessive ectopia lentis (310).

### 153.6.3 Loeys–Dietz Syndrome (OMIM 609192)

Some patients originally diagnosed as MFS were investigated from a molecular perspective because they lacked mutations in *FBN1* and showed features atypical of MFS, such as hypertelorism, bifid uvula or actual cleft palate, intellectual delay, and tortuosity (unwinding) of the thoracic aorta and other arteries with dilation and dissection (121,285,311). This condition is due to mutations in two of the receptors for TGF- $\beta_1$ , *TGFBR1* and *TGFBR2*.

Skeletal features that are particularly common include talipes equinovarus, atlantoaxial instability, scoliosis, spondylolithesis and dural ectasia (312). Patients do not have or develop ectopia lentis. Some develop autoimmune disorders of the gastrointestinal system. Aortic dissection tends to occur at smaller aortic root diameters than in MFS, so patients need to undergo prophylactic repair at younger ages (if children) and at diameters around 40mm in adults (266,313).

### 153.6.4 Familial Aortic Aneurysm and Dissection (OMIM 132900, 607086, 607087, 611788, 613780)

Familial, non-syndromic disease of the thoracic aorta, whether predisposing to aneurysm or dissection Thoracic aortic aneurysms and dissections (TAAD), is much more common than generally recognized (314,315). While inheritance may not be clear from the small pedigrees that come to attention clinically, in many families

predisposition to thoracic aortic disease is an autosomal dominant trait (316). Analysis of fibroblast cultures of skin or aorta in some patients has revealed mutations of *FBN1* in a few cases (183,316,317). However, mutations in *FBN1* and *COL3A1* account for a small minority of such families (318,319). Linkage analyses in families has identified a number of loci (320–323), including *TGFBR1* and *TGFBR2* (Table 153-8). For these two genes, the most severe end of the phenotypic spectrum is the Loeys–Dietz syndrome (*vide supra*), but some families have features largely restricted to the thoracic aorta. In families with *TGFBR1* mutations, men died earlier from TAAD, whereas females tended to develop aneurysms and dissections of branch arteries. In families with *TGFBR2* mutations, while the genders behaved similarly, type A dissection occurred in aortic roots dilated less than 50 mm (324).

In a large Dutch family, in which arterial aneurysms and dissections co-segregated with osteoarthritis of early onset, a mutation in *SMAD3* was found (325). This mutation, and two others in two additional families with the same phenotype, all disrupted the MH2 domain of the *SMAD3* protein, which is crucial for proper oligomerization with *SMAD4*. Presumably, TGF- $\beta$ -mediated gene activation is impaired.

In an important change in the way we think about these conditions, Dr. Dianna Milewicz and colleagues recognized that mutations in three genes (*ACTA2*, *MYH11*, and *MYLK*) disrupt intracellular cytoskeletal molecules and their interactions with integrins and the ECM in vascular smooth muscle cells (326,327). Many mutations predispose not only to dilatation of the thoracic aorta and occasionally cerebral arteries, but non-atherosclerotic occlusion of coronary, cerebral and visceral arteries (327).

### 153.6.5 Arterial Tortuosity Syndrome (OMIM#208050)

The condition initially was described in infants, often from consanguineous families. Some of the young patients had features of cutis laxa, and many died in early childhood from a variety of cardiovascular problems including stroke and severe peripheral pulmonic stenoses. Eventually adults were recognized with the same, albeit milder, phenotype including marked elongation and tortuosity of the aorta and its major branches, and a variety of signs of a systemic connective tissue disorder (joint hypermobility, soft, doughy skin) (328). The typical facial features include an elongated face, retrognathia, down-slanting palpebral fissures, blepharophimosis and a beaked nose (329).

Arterial tortuosity was mapped in consanguineous families to 20q13 (330,331). Mutations in the gene (*SLC2A10*) encoding a nuclear glucose transporter, *GLUT10*, were found in several patients (329). Obligate heterozygotes have normal vasculature. The pathogenesis

seems to involve transcriptional regulation of several ECM proteins that regulate TGF $\beta$  signaling; with the result that TGF $\beta$  activity is accentuated in the vascular wall.

### 153.6.6 Phace(s) Association (OMIM 606519)

Another condition with multiple anomalies, known by the acronym PHACE(S) association (posterior fossa abnormalities of the brain, hemangiomas, arterial, cardiac, and eye defects, and sternal clefts), predisposes to arterial tortuosity, aortic dilation, and aortic rupture (332,333). The association overwhelmingly affects females, no familial instances are reported, and the etiology is unknown.

### 153.6.7 Bicuspid Aortic Valve (OMIM 109730)

The tetrad of bicuspid aortic valve, coarctation of the aorta, MVP, and ascending aortic aneurysm is increasingly well recognized as autosomal dominant with variable expression (334). In some families, one or more of the aortic findings occur in relatives of a proband with a more severe, congenital left-sided flow defect, such as hypoplastic left heart. In patients ascertained through a bicuspid aortic valve, defects of the ascending aortic wall should be considered (335–338). The dilatation typically spares the sinues (in distinction to MFS), and is most pronounced in the mid-ascending aorta and into the arch. Because transthoracic (i.e. standard) echocardiography often does not visualize the mid-ascending aorta, patients with a bicuspid aortic valve should have a CT or MR of the thorax to establish if dilatation is present, and if so, to be followed by an adequate imaging modality. The histopathology of the aortic wall typically shows medial degeneration, indistinguishable from MFS. In aortic media in both conditions, the C-terminal fragment of filamin A is abundant, likely due to increased activity of the protease, calpain A (339).

Bicuspid aortic valve clearly predisposes to type A dissection because of the involvement of the ascending aorta, but the criteria for when to operate solely for the aneurysm (rather than a dysfunctional valve) are not well established. In many instances of relatively normal valve function, a valve-sparing ascending aortic repair, typically involving hemi-arch replacement, is feasible. The long-term outlook of such cases, especially with regard to function of the aortic valve, remains to be determined. Similarly, any patient who is to undergo surgery for a dysfunctional bicuspid aortic valve should be considered for concomitant aortic root repair, especially if the maximal diameter exceeds 45 mm (340,341). Because the embryological derivation of the pulmonary and aortic trunks is the same, the Ross procedure is not the best treatment for patients who require surgery for their aortic valve and aortic root disease (342,343).

**TABLE 153-8 Human Hereditary Aneurysm Conditions and Murine Models of Aneurysm**

Gene (Protein)	Human Aneurysmal Syndrome	Animal Model Phenotype	Pathway Implicated
<i>Extracellular matrix protein</i>			
<i>FBN1</i> (fibrillin-1)	Marfan Syndrome – Fully penetrant ascending aortic aneurysm	KO: Perinatal lethality, Pulmonary hypoplasia, arteriopathy Hypomorphic: Arteriopathy, aneurysm, dissection	TGFβ
<i>EFEMP2</i> (fibulin-4)	Cutis Laxa with Aneurysm – Ascending aortic aneurysm and tortuosity	KO: Ascending aortic aneurysm, defective elastogenesis, perinatal lethality Sm22-Cre (smooth muscle) KO: Ascending aortic aneurysm	TGFβ
<i>ELN</i> (Elastin)	Cutis Laxa with Aneurysm- low penetrance ascending aortic aneurysm and dissection	Haploinsufficient: Obstructive arterial disease with increased VSM proliferation, increased lamellae number KO: Accentuated phenotype	Unknown
<i>COL1A1</i> (Collagen 1 alpha-1)	Osteogenesis Imperfecta – extremely rare aortic aneurysm Ehlers Danlos Syndrome, type 7A- dissection of medium size arteries	KO: Adult onset aortic aneurysm and dissection	Collagen Metabolism
<i>COL1A2</i> (Collagen 1 alpha-2)	Osteogenesis Imperfecta – extremely rare aortic aneurysm Ehlers Danlos Syndrome–cardiac valvulodystrophy type 7B– borderline aortic root enlargement with aortic regurgitation	Homozygous LOF: Decreased body weight, bony abnormalities, no arterial phenotype reported	Collagen Metabolism
<i>COL3A1</i> (Collagen 3 alpha-1)	Ehlers–Danlos, type 4 – frequent arterial dissection with infrequent aneurysm	KO: Frequent neonatal mortality, aortic rupture, intestinal rupture	Collagen Metabolism
<i>COL4A1</i> (Collagen 4 alpha-1)	Hereditary angiopathy, nephropathy, aneurysms, and muscle cramps – infrequent aneurysms	KO: Embryonic lethal (E10.5-11.5), basement membrane failure	Collagen Metabolism
<i>COL4A5</i> (Collagen 4 alpha-5)	X-linked Alport syndrome – ascending aortic and abdominal aneurysms and dissections	Nonsense mutation: No overt aortic disease noted	Collagen Metabolism
<i>LOX1</i> (lysyl oxidase 1)	No human phenotype described	KO: Low penetrance aortic aneurysm, perinatal lethality	Collagen Metabolism TGFβ
<i>PLOD1</i> (lysyl hydroxylase 1)	Ehlers–Danlos, type 6–rare aneurysm	KO: Spontaneous aneurysm and dissection, gait abnormalities	Collagen Metabolism
<i>PLOD3</i> (lysyl hydroxylase 3)	Bone Fragility with Contractures, Arterial Rupture, and Deafness – frequent medium sized arterial aneurysms	KO: Embryonic lethality (E9.5) and basement membrane fracture	Collagen Metabolism
<i>Transmembrane protein</i>			
<i>TGFBR1</i> (tgfb1)	Loeys–Dietz Syndrome – highly penetrant root and diffuse large and medium arterial aneurysm	KO: Midgestational death with yolk sac defects M318R heterozygous knock in: Aortic Root and diffuse aneurysm (D. Loch, unpublished observations)	TGFβ
<i>TGFBR2</i> (tgfb2)	Loeys–Dietz Syndrome - highly penetrant root and diffuse large and medium arterial aneurysm FTAAD - highly penetrant root and medium arterial aneurysm	KO: Defects in hematopoiesis and vasculogenesis, lethal (E10.5), <i>TGFBR2</i> flox: Impaired elastogenesis, decreased lysyl oxidase in aorta G457W heterozygous knock in: Aortic Root and diffuse aneurysm (D. Loch, unpublished observations)	TGFβ
<i>SLC2A10</i> (Glucose transporter 10)	Arterial Tortuosity Syndrome – diffuse arterial tortuosity, stenoses, aneurysms	Homozygote missense: Arterial Thickening with increased elastin deposition, elastin fractures at advanced age	TGFβ
<i>NOTCH1</i> (notch1)	Bicuspid Valve with ascending aortic aneurysm	KO: Embryonic lethal (E9.5) Required for somite segmentation, defects in angiogenesis.	NOTCH/ Jagged1
<i>JAG1</i> (jagged1)	Alagille Syndrome – intracranial aneurysms, coarctation of the aorta, aortic aneurysm	KO: Embryonic lethal (E9.5) with diffuse hemorrhages	NOTCH/ Jagged1
<i>PKD1</i> (polycystin-1)	Polycystic Kidney Disease with intracranial aneurysms	KO: Embryonic lethal (E14.5) with polycystic kidneys Hypomorphic expression: Adult onset aortic aneurysm and dissection	Unknown
<i>PKD2</i> (polycystin-2)	Polycystic Kidney Disease with intracranial aneurysms	KO: Defects in cardiac septation and left-right axis determination, kidney and pancreatic cysts	Unknown

**TABLE 153-8 Human Hereditary Aneurysm Conditions and Murine Models of Aneurysm—cont'd**

Gene (Protein)	Human Aneurysmal Syndrome	Animal Model Phenotype	Pathway Implicated
<i>GJA1</i> (connexin 43)	Hypoplastic Left Heart Syndrome (HLHS)	Nonsense (W45X): Coronary artery aneurysms	Unknown
<i>ENG</i> , <i>ACVRL1</i>	Hereditary hemorrhagic telangiectasia— dilated ascending aorta in some adults; arteriovenous malformations common	<i>Eng</i> and <i>Acvrl1</i> KO: aorta not evaluated	? BMP
<i>Cytoplasmic proteins</i>			
<i>ACTA2</i> ( $\alpha$ -smooth muscle actin)	Familial Aortic Aneurysm with levido reticularis and iris flocculi	KO: Viable offspring with normal life span and impaired vascular contractility	IGF-1, Ang2
<i>MYH11</i> (smooth muscle myosin)	Familial Aortic Aneurysm with patent ductus arteriosus	KO: Neonatal lethality, urinary retention, dilated cardiomyopathy	IGF-1, Ang2
<i>FLNA</i> (Filamin A)	Periventricular Nodular Heterotopia with Ehlers–Danlos features – ascending aortic aneurysm and valvular dystrophy	KO: Neonatal lethality, Persistent Truncus Arteriosus, endothelial cell-cell contact defects	Unknown
<i>NF1</i> (Neurofibromin 1)	Neurofibromatosis - medium sized arterial aneurysm and stenosis	KO: Enlarged head, pale liver, cardiac malformations	Ras/MEK/ ERK
<i>PTPN11</i> (SH2 domain-containing protein tyrosine phosphatase-2)	Noonan and LEOPARD Syndrome – coronary artery aneurysms and rare ascending aortic aneurysm	KO: Embryos die preimplantation Missense (D61G): Cardiac defects, defective valvulogenesis, skeletal anomalies, myeloproliferative disorder	Ras/MEK/ ERK
<i>NPHP3</i> (Nephrocystin-3)	Nephronophthisis	KO: Low penetrance intracranial aneurysms	Unknown
<i>NOS3</i> (Nitric Oxide Synthetase 3)	Refractory hypertension	KO: Abnormal aortic development with BAV, in combination with ApoE–/–, mice show abdominal arterial aneurysm and dissections	NO
<i>TSC2</i> (tuberin)	Tuberous Sclerosis – Diffuse thoraco- abdominal aneurysms	Heterozygous KO: Increased proliferation of VSMCs upon injury	mTOR/ AKT
<i>GAA</i> ( $\alpha$ -1, 4-glucosidase)	Acid Maltase Deficiency, adult onset – intracranial aneurysms	KO: Lysosomal accumulation in heart, aorta, skeletal muscle	Unknown
<i>S100A12</i> ( <i>S100A12</i> )	No Human Phenotype, increased <i>S100A12</i> expression in human MYH11 aneurysmal tissues	Sm22 $\alpha$ promoter-S100A12 Transgenic mouse: VSM disarray, elastin fragmentation, thoracic aneurysm	TGF $\beta$ , IL-6
<i>Nuclear proteins</i>			
<i>MED12</i> (mediator complex subunit 12)	Lujan–Fryns Syndrome—extremely rare aneurysm	Hypomorphic mutants: Embryonic lethal (E10), defects in neural tube closure, somatogenesis, heart formation	Wnt/ $\beta$ - catenin, Wnt/PCP
<i>KLF15</i> (Kruppel-like factor 15)	No Human Phenotype, <i>Kruppel-like factor</i> 15 downregulated in human abdominal aortic aneurysm	KO: Aortic aneurysm and cardiomyopathy	TSP-1, p53
<i>KLF2</i> (Kruppel-like factor 2)	No Human Phenotype	KO: Embryonic aortic aneurysm and dissection	Unknown
<i>SMAD3</i>	Aortic aneurysm, osteoarthritis	KO: colorectal adenocarcinoma; immune dysfunction	TGF $\beta$
<i>Inborn errors of metabolism</i>			
<i>GLA</i> ( $\alpha$ -galactosidase A)	Fabry disease—dilatation of ascending aorta common	Gla-deficient mice	Unknown
<i>GAA</i> ( $\alpha$ -1, 4-glucosidase)	Pompe disease, adult onset – intracranial aneurysms	KO: accumulation of glycogen in lysosomes in heart, aorta, skeletal muscle	Unknown
<i>Chromosomal anomaly</i>			
45 X,0	Turner Syndrome – Bicuspid aortic valve, coarctation of the aorta, ascending aneurysm	XO mice demonstrate no phenotypic heart disease	Unknown
<i>Chemical models</i>			
	No human phenotype	Ang2 infusion model	Ang2, TGF $\beta$ MCP-1, IL-6
	No human phenotype	Elastase infusion model	Unknown
	No human phenotype	Periarterial calcium application	JNK1

Adapted from Lindsay et al. (142) with permission and appreciation.

In two families with multiple members having bicuspid aortic valve as well as other congenital heart defects, mutations in *NOTCH1* were found (344). Screening many additional subjects with a bicuspid valve, with or without an aneurysm or a family history, has failed to detect other mutations in *NOTCH1*. A genome-wide linkage study in 353 individuals from 38 families found evidence for linkage to 18q, 5q and 13q, with the strongest signal at 18q22 (345).

### 153.6.8 Familial Intracranial Aneurysm (OMIM 105800)

Intracranial (berry) aneurysms have long been known to be familial. In some cases, the underlying cause is adult polycystic kidney disease (345). In other pedigrees, the phenotype was linked to 19q13.3 (346).

### 153.6.9 Abdominal Aortic Aneurysm (OMIM 100070)

In most cases, the pathology of aneurysms of the abdominal aorta (AAA) is quite distinct from aneurysm and dissection of the thoracic aorta, with evidence of inflammation being much more prominent in the abdomen. There is a substantial literature showing the familial occurrence of AAA, but most studies have concluded that multifactorial inheritance is most consistent with the pedigrees (347). However, some pedigrees suggest autosomal dominant inheritance and some pedigrees showed linkage to 4q31 and 19q13 (348). Interestingly, this latter locus is the same region identified for intracranial aneurysms. More recently, a genome-wide association study found strong association between AAA and markers at 3p12.3 (349).

### 153.6.10 Rare Familial Cardiovascular Disorders

Familial occurrence of calcific aortic disease (OMIM 114065) and fibromuscular dysplasia (OMIM 135580) (330) are of unclear etiology but could well be attributable to abnormalities of the elastic fiber, microfibrils, or the small molecules they influence. Supravalvular aortic stenosis (OMIM \*185500) is due to mutations in the *ELN* locus at 7q11.2 encoding tropoelastin. A contiguous gene deletion in this region causes Williams syndrome (OMIM 194050; see Chapter 45).

### 153.6.11 Familial Tall Stature

Tall stature unassociated with other skeletal abnormalities (except in the proband) is linked to *FBN1* in one pedigree (193). A point mutation, causing R1828W, seems to result in failure to cleave the C-terminal propeptide, and segregates with tall stature in this family. Milewicz and colleagues suggested that this mutation creates, in essence, a null allele, and that the patients have simply a

50% reduction in fibrillin-1 in the ECM. This interesting hypothesis needs to be confirmed by both biochemical analysis and sequencing of the other *FBN1* allele.

### 153.6.12 Familial Kyphoscoliosis

A point mutation in *FBN1*, G1796E, co-segregated with tall stature, pectus excavatum, kyphoscoliosis, and mild vertebral dysplasia in one family, all of whose members lacked ocular or cardiovascular evidence of MFS (350).

### 153.6.13 Familial Pneumothorax

To complete the spectrum of autosomal dominant traits involving predominantly one of the cardinal systems of classic MFS, the uncommon disorder familial pneumothorax was examined in three pedigrees for linkage to the *FBN1* locus. Each family showed autosomal dominant inheritance, with one instance of nonpenetrance in one family. None of the affected individuals showed any outward evidence of a connective tissue disorder. A common *FBN1* haplotype failed to segregate with the phenotype in all three families, indicating that mutations in *FBN1* do not account for this disorder (351). In a large Finnish pedigree, spontaneous pneumothorax was inherited as an autosomal dominant trait with complete penetrance and no other clinical features. Linkage analysis localized the gene to 17p11, and screening of candidate loci for mutations identified a 4-bp deletion in *FLCN* (352), mutations in which had previously been found in Birt-Hogg-Dubé (BHDS) syndrome (OMIM #135150). In BHDS, cystic lung disease is associated with fibrofolliculomas of the skin, and renal carcinoma.

### 153.6.14 Shprintzen–Goldberg Syndrome (OMIM \*182212)

As originally described, the phenotype consists of craniosynostosis (associated with exophthalmos), mandibular and maxillary hypoplasia, arachnodactyly, camptodactyly, hemias, muscular hypotonia, and developmental delay (353). Additional cases of this rare disorder have emphasized both the range of skeletal abnormalities (highly arched palate, pectus carinatum or excavatum, dolichostenomelia) and involvement of the cardiovascular system (354–357). Several patients with this phenotype, clearly well beyond the limits of MFS, have developed marked aortic dilation or dissection (355,358). A mutation in *FBN1* has been found in two patients (358,359), and some of the other reported patients might well have Loeys–Dietz syndrome (359).

### 153.6.15 Congenital Contractural Arachnodactyly (OMIM \*121050)

CCA is defined primarily by abnormalities of the skeletal system inherited as an autosomal trait.

Contractures, most severe at birth, typically affect the digits of the feet and hands, knees, and elbows. The contractures tend to improve with age and with physical therapy, unless pterygia are present. Scoliosis, often with accentuated kyphosis, develops during childhood and adolescence and can become severe. The only consistent, non-skeletal manifestations are mild hypoplasia of the calf muscles and ‘crumpling’ of the ear helix (360). In one pedigree, CCA was associated with intraocular colobomas. Ectopia lentis, aortic dilation, and myxomatous degeneration of the mitral valve, if present, suggest a diagnosis of MFS. Indeed, numerous patients have been reported as ‘contractural arachnodactyly’ with cardiovascular disease who undoubtedly had classic MFS (361,362). On the other hand, aortic dilation can occur in patients with CCA and mutations in *FBN2* (363). In the ultimate irony, Gabrielle P., Marfan’s first patient may have had CCA (42). Mild to moderate folding with foreshortening of the helix is fairly common in the general population and may be increased in MFS. As noted earlier, congenital contractures of the digits and elbows (but rarely the knees) are also common in MFS. One distinction may be the observation that the contractures of CCA improve, especially with physical therapy, whereas those associated with MFS usually do not. No comprehensive studies of anthropometrics have been performed in CCA. Thus description of dolichostenomelia, arachnodactyly, and ‘marfanoid’ habitus are based on clinical perception and not objectivity.

Several pedigrees were linked to *FBN2* on chromosome 5q23–31 (20). Several dozen mutations have been found in unrelated patients (221,364,365) and are cataloged at: [www.umd.be/FBN2](http://www.umd.be/FBN2). Two sibs with especially severe manifestations were the products of a double second-cousin mating, raising the possibility of an autosomal recessive form.

### 153.6.16 Lujan–Fryns Syndrome (OMIM 309520)

One of the most commonly – and incorrectly – used descriptors in clinical genetics is the term **marfanoid**. Typically, the word is used for anyone who appears tall and slender with an elongated face and dolichostenomelia. The appearance of ‘marfanoid’ in a consultant’s report is often enough to prompt the primary care physician to request a genetic evaluation; in my experience, few such individuals have Marfan syndrome, so the predictive value of a ‘marfanoid habitus’ seems quite low (292). There are good reasons to suggest that the term should be discarded altogether.

‘Marfanoid’ was used to describe males who were initially ascertained on account of mental retardation (366). Those affected were not actually tall, but were slender, had elongated arms, and had characteristic craniofacial features of a long narrow face, retrognathia,

and a highly arched palate. Inheritance was consistent with X-linkage. Fryns (367) reported several cases, and the condition is commonly called Lujan–Fryns syndrome. For the reasons noted previously, this is preferable to the other name, X-linked mental retardation with marfanoid habitus. In one institutionalized population of mentally retarded adults, 5% of males had a form of X-linked mental retardation, and 10% of them had Lujan–Fryns syndrome (368). In addition to retardation, most, but not all, patients have neurobehavioral abnormalities (369). Subsequently, the phenotype has been reported in occasional female relatives of probands. Few patients have had comprehensive cardiovascular evaluation, which should be performed given the report of ventricular septal defects and aortic root dilation in two relatives with Lujan–Fryns (370).

Several probands have mutations in the *MED12* gene, and the mutation segregates with the condition in the families (371). Lujan–Fryns syndrome is thus allelic with Opitz–Kaveggia syndrome (OMIM 305450).

### 153.6.17 Weill–Marchesani Syndrome (OMIM \*277600; 608328)

Weill–Marchesani syndrome (WMS) is a condition long classified as an autosomal recessive trait because of multiple affected sibs of consanguineous parents and its occurrence among inbred populations (85). However, an increasing number of pedigrees consistent with autosomal dominance are being observed (372–374). The phenotype is characterized by ocular and skeletal changes that are in many respects the antithesis of MFS. The lens is ectopic, but usually spherophakic. Stature is below average, the digits are short, and the joints are stiff. A few cardiovascular problems have been noted, including pulmonic stenosis and subvalvular aortic stenosis, but these findings have been inconsistent. Reduced ability to open the mouth and maxillary hypoplasia can impair anesthetic management of the airway (375). Review of the phenotypes in reported families that showed both recessive and dominant inheritance detected no important distinctions (373).

By homozygosity mapping in an inbred Lebanese/Saudi pedigree, a locus causing recessive WMS was mapped to 19p13.3–p13.2 (376). Mutations in *ADAMTS10*, a locus in this region that encodes a disintegrin and metalloproteinase, were found in several families with recessive WMS (377).

After staining for fibrillin, decreased immunofluorescence of the dermal-epidermal junction and the deep dermis was found in skin from a patient of the family described by Gorlin and colleagues (375). This same biopsy showed an apparent increase in elastic fibers. Linkage studies found the autosomal dominant form to map to 15q, close to *FBN1*, and an in-frame deletion was found (373,378,379).

### 153.6.18 Stiff Skin Syndrome (OMIM #184900)

Rare patients have hardened, thickened skin over their entire body; autosomal dominant inheritance is clear in some families. The skin changes can limit ambulation and cause flexion contractures. Skin biopsy analysis showed increased deposition of both fibrillin and elastin (380). Sequencing of *FBN1* found mutations in a number of patients, including one who had stiff skin and ectopia lentis.

The tight skin mouse is heterozygous at the *Tsk* locus, which is syntenic with human chromosome 15. The original mouse strain has a large genomic duplication within the *Fbn1* locus (381).

### 153.6.19 Multiple Self-Healing Squamous Epithelioma (MSSE) (OMIM #132800)

This condition was first described by a British dermatologist in a Scotsman, and most cases have been found in that country (382). This autosomal dominant disorder is characterized by benign but invasive squamous epitheliomas that arise spontaneously (especially on sun exposed skin) and regress over a period of weeks to months. Depressed scars, which can be cosmetically unappealing, result. Variable expressivity and even apparent non-penetrance occur. The dermatologist's son, the noted human geneticist Malcom Ferguson-Smith, worked assiduously over several decades to map the locus. These investigations culminated with the discovery of mutations in *TGFBR1*, but of a type distinct from those that cause Loeys-Dietz syndrome and familial thoracic aortic aneurysm (383). The mutations in patients with MSSE occur predominantly in the receptor domain with some in the kinase domain (the latter being truncating mutations), whereas those causing Marfan-related disorders occur solely in the kinase domain and are predominantly missense. Interestingly, analysis of the DNA from lesions of MSSE shows loss of the normal allele. Thus, *TGFBR1* functions as a tumor suppressor.

### 153.6.20 Acromicric (OMIM#102370) and Geleophysic (OMIM#231050) Dysplasias

These two conditions share phenotypic features but acromicric dysplasia is autosomal dominant while geleophysic dysplasia is autosomal recessive. Both have marked short stature, prominent shortening of the hands and feet, thick skin and limited joint range of motion. About half of all patients with geleophysic dysplasia have mutations in *ADAMTSL2* (OMIM#612277). Mutations in exons 41 and 42 of *FBN1* affect the TGF $\beta$ -binding protein-like domain 5, and cause several syndromes (Table 153-6), including both of these skeletal dysplasias (211). Along with Weill-Marchesani syndrome, they represent the antithetical phenotype of the Marfan syndrome caused by mutations in the same gene.

## ACKNOWLEDGMENTS

This revision was accomplished during a time of support by the National Heart, lung and Blood Institute (Gen-TAC) and the National Human Genome Research Center (Center of Excellence in ELSI Research P50-HG-004487), both of the US National Institutes of Health, and while in residence at the Brocher Foundation, Hermance, Switzerland. I also thank all of my colleagues who shared their published and unpublished work and commented on sections of the chapter, especially Harry C. Dietz, M.D. and Irene H. Maumenee, M.D.

### Biography

Reed Pyeritz completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

## Ehlers–Danlos Syndrome

Peter H Byers

Department of Pathology, University of Washington, Seattle, WA, USA

This article is a revision of the previous edition article by Peter H Byers and Ulrike Schwarze, volume 3, pp 3625–3646, © 2007, Elsevier Inc.

### 154.1 INTRODUCTION

Ehlers–Danlos syndrome (EDS) is a group of disorders characterized by abnormalities of skin, joints, and other connective tissues (1–3) (Table 154-1). Early descriptions of these disorders emphasized joint laxity and skin hyperextensibility (4,5), but as more patients were identified, skin fragility, easy bruising, and the occasional complication of arterial and bowel rupture were recognized (6,7a,8). This clinical heterogeneity has been explained, in part, by biochemical and molecular genetic dissection of the underlying mechanisms. An attempt, in 1997, to integrate the clinical, biochemical, and molecular genetic studies provided a more descriptive classification than the previous numeric one (9). Additional studies since that time suggest that further amplification of the nosology is warranted. Table 154-1 provides the older (numerical) and current (descriptive) classification, a summary of the molecular genetic studies, and proposal for additional types of EDS based on recent studies.

This chapter summarizes the clinical, genetic, and biochemical features of recognized EDS types, provides a summary of the details of collagen structure, biosynthesis, and tissue distribution that serves as the basis for understanding the molecular mechanisms of some of these disorders, and discusses recent findings that expand the clinical and molecular realms of EDS.

### 154.2 COLLAGEN GENES AND PROTEINS

The collagens form a family of evolutionarily related and structurally similar proteins that have a signature amino acid sequence (the repeating triple helical sequence of Gly-Xaa-Yaa, in which Xaa and Yaa can be almost all other amino acids but are often proline), the characteristic amino acids hydroxyproline and hydroxylysine that result from post-translational modification, and form

trimeric molecules that contain the same chains or closely related chains that form a collagen triple helix. The genes that encode collagens are under tight tissue- and cell-specific control so that each collagen has a characteristic distribution (10a,11,12a). The family of collagen genes is divided into several distinct lineages that encode proteins with different distributions and structures. The major lineage is the fibrillar collagens, which are encoded by a set of nine closely related genes (*COL1A1*, *COL1A2*, *COL2A1*, *COL3A1*, *COL5A1*, *COL5A2*, *COL5A3*, *COL11A1*, and *COL11A2*) that form three clades (13,14). These genes encode the chains of types I, II, III, V, and XI collagens. Types II and XI are expressed in cartilage and mutations in those, unlike mutations in the other genes, do not give rise to EDS phenotypes.

Ehlers–Danlos syndrome phenotypes are known to result from mutations in the *COL1A1* and *COL1A2* genes of type I collagen, the *COL3A1* gene of type III collagen, and the *COL5A1* and *COL5A2* genes of type V collagen. Mutations in genes that encode proteins responsible for post-translational modification of some collagens produce EDS phenotypes. These genes include *PLOD1*, which encodes the modifying enzyme lysyl hydroxylase 1, and *ADAMTS2*, which encodes the pro-collagen I N-proteinase. In addition, it has become clear that mutations in other genes that express proteins found in the extracellular matrix or modify matrix proteins can also produce similar clinical phenotypes.

The genes for all fibrillar collagens are complex and contain between 50 and 66 exons. Each gene encodes a protein that contains a signal sequence, an amino-terminal propeptide, a triple helical domain, and a carboxyl-terminal propeptide. The triple helical domain is characterized by a repeating Gly-Xaa-Yaa motif (in which glycine (Gly) is in every third position and Xaa and Yaa can be any amino acid except tryptophan and cysteine). In each chain of the fibrillar collagens, there are

**TABLE 154-1 Clinical Features, Mode of Inheritance, and Biochemical Disorder in Ehlers–Danlos Syndrome**

Descriptive Type	Clinical Features	Inheritance <sup>a</sup>	Molecular Defect
Classical type	Soft, velvety, hyperextensible skin; easy bruising; joint hypermobility; “cigarette paper” scars; prematurity	AD	<i>COL5A1</i> and <i>COL5A2</i> mutations (EDS type I and II)
	Soft hyperextensible skin, joint hypermobility, abnormal scars, cardiac valvular abnormalities, aortic dilatation	AR	<i>COL1A2</i> null alleles
	Soft hyperextensible skin, joint hypermobility, abnormal scars	AD	<i>COL1A1</i> R136C (rare)
	Soft hyperextensible skin, normal scarring, joint hypermobility	AR	<i>TNXB</i> null mutations
Hypermobile type	Soft skin, no scarring, marked large and small joint hypermobility	AD	Most not known (EDS type III). Heterozygosity for <i>TNXB</i> null mutations (rare: <i>COL3A1</i> G637S)
Vascular type	Thin, translucent skin with visible veins; marked bruising; skin and joints have normal extensibility; arterial, bowel, and uterine rupture	AD	Mutations in the <i>COL3A1</i> gene (EDS type IV) that alter type III collagen synthesis, secretion, and structure
Kyphoscoliotic type	Soft, velvety, hyperextensible skin; hypermobile joints, scoliosis; ocular fragility and keratoconus	AR	Lysyl hydroxylase deficiency due (EDS type VI) to mutations in the <i>PLOD1</i> gene
Arthrochalasia type	Congenital hip dislocation, joint hypermobility; soft skin with normal scarring	AD	A: <i>COL1A1</i> exon 6 splice site (EDS type VIIA) mutations that delete N-proteinase cleavage site from the protein B: <i>COL1A2</i> exon 6 splice site mutations that delete N-proteinase cleavage site from the protein
Dermatosparaxis	Very soft, fragile, bruisable skin, marked joint hypermobility, blue sclera, small jaw, hypertrichosis	AR	<i>ADAMTS2</i> mutations that result in (EDS type VIIC) loss of procollagen N-proteinase activity
Other Types of Ehlers–Danlos Syndrome			
X-linked (EDS type V)	Soft, velvety, hyperextensible skin, hypermobile joints, bruising with muscle hemorrhage, abnormal scars	XLR	Not known (single family)
Periodontal type	Soft hyperextensible skin, mild scarring, mild joint hypermobility, pretibial bruising and heme pigmentation, generalized periodontal loss with early tooth loss	AD	One locus at 12p13 (EDS type VIII); probably genetically heterogenous
Fibronectin deficiency	Soft skin, mild hypermobility, bruising, platelet aggregation defect	?AR	Defect in fibronectin (single family)
Progeroid type	Progeroid facies, multiple nevi, mild mental retardation, skin hyperextensibility, bruisability, moderate skin fragility, joint hypermobility principally in digits, with radio-ulnar synostosis and developmental delay	AR	Mutations in <i>B4GALT7</i> that encodes galactosyltransferase-I
EDS with brain heterotopias	Soft, hyperextensible skin, joint hypermobility, seizures, arterial aneurysms	XLD	Mutations in <i>FLNA</i> gene that encodes the filamin A protein

<sup>a</sup>AD = autosomal dominant; AR = autosomal recessive; XLD = X-linked dominant; XLR = X-linked recessive.

just over 1000 amino acid residues in the triple-helical motif that has no interruptions in the triplet structure.

### 154.3 BIOSYNTHESIS OF COLLAGENS

The biosynthesis of collagen molecules involves many steps beyond gene transcription. The 50 or more exons of the fibrillar collagen genes are arrayed over 18–500 kbp. The *COL1A1* is the smallest of the fibrillar collagen while the *COL5A1* gene is the largest. The majority of

the others have gene sizes between 40 and 60. The genes are transcribed and spliced in the nucleus; the mature mRNAs of 4800–7200 nucleotides are transported to the cytoplasm where they are translated on membrane-bound polysomes. Each chain is initiated with a signal sequence that facilitates cotranslational insertion into the lumen of the rough endoplasmic reticulum (RER) and is cleaved shortly after entry into the lumen. The precursor chains (pro $\alpha$  chains) of the fibrillar collagens are 1350–2000 amino acids in length.

As cotranslational and post-translational events, certain lysyl residues in the Y-position of the triple helix, and virtually all Y-position prolyl residues, are hydroxylated by the enzymes lysyl hydroxylase (encoded by *PLOD1*), and prolyl-4-hydroxylase (which is a heterotetramer made up of two chains each of the  $\alpha$  and  $\beta$  subunits that are encoded by *P4HA* and *P4HB*, respectively) (15). These enzymes are encoded by distinct genes but share cofactors (ferrous iron, ascorbate or other reducing compounds, and  $\alpha$ -ketoglutarate). Prolyl-4-hydroxylase is located within the lumen of the RER and the  $\beta$ -subunit is identical to disulfide isomerase, a protein that catalyzes interchain and intrachain disulfide bond formation during protein folding and chain association. Lysyl hydroxylase is located in the membrane of the RER. The degree of both prolyl and lysyl hydroxylation varies in different collagen types and may vary from tissue to tissue for the same collagen. Following hydroxylation, some hydroxylysyl residues are glycosylated to form glucosyl-galactosylhydroxylysyl or galactosylhydroxylysyl residues (16), and oligosaccharide is added to a single asparagine residue in the C-terminal propeptide of each chain.

When the synthesis of each pro $\alpha$  chain is complete, the carboxyl-terminal propeptide of each chain folds and is stabilized by intrachain disulfide bonds. Each chain has a specific region that appears to function as a chain recognition domain (17), which determines the manner in which chains assemble into the procollagen molecule of each type. The three constituent chains of each procollagen first interact with each other at sites within the C-terminal propeptide, the association is stabilized by interchain disulfide bonds, and triple helix is propagated toward the N-terminal end of the molecules. Post-translational hydroxylation and glycosylation of residues in the triple-helical core domain cease when a stable triple helix is achieved. In turn, the stability of the triple helix is dependent on complete hydroxylation of the Y-position prolyl residues. Upon formation of the stable triple helix, the procollagen molecule is transported to the Golgi and then to the cell surface. Once secreted, fibrillar procollagen molecules are processed to collagen by proteolytic cleavage with specific proteases that remove the amino-terminal and carboxyl-terminal propeptides.

The extracellular molecules assemble into fibrils and other higher-order structures, where they become covalently cross-linked to form highly stable polymers. It now appears likely that the major collagen fibrils in the extracellular matrix of skin and many other tissues are largely type I collagen, and depend on a small core of type V collagen molecules for initial formation (18). The cross-links are formed following oxidative deamination of lysyl or hydroxylysyl residues located just outside the triple-helical domains, to produce highly reactive aldehydes (19). Lysyl oxidase, a copper-containing enzyme, initiates this process (20a,21a). The activated residues can form multifunctional cross-links that stabilize fibrils and higher-order aggregates (19). The structure of the

collagen fibril, its aggregation into bundles, and the mechanical properties of tissues depend on cross-links and on interactions with several other macromolecules, most notably proteoglycans and other glycoproteins.

## 154.4 CLASSICAL EHLERS–DANLOS SYNDROME (TYPES I AND II—GRAVIS AND MITIS)

### 154.4.1 Clinical Aspects

The revised classification of EDS groups the previously distinct EDS type I and EDS type II as the “classical” variety. This clinical group clearly represents a genetically heterogeneous group of disorders. The clinical distinctions among the groups that have mutations in different genes are not yet well defined. The majority of individuals within this group appear to have mutations that affect the expression or structure of type V collagen with most in the *COL5A1* gene and a smaller number in the *COL5A2* gene. A second group has “null” mutations in the *COL1A2* gene, for which they are either homozygous or compound heterozygotes. A third set has mutations in the *TNX* gene that encodes the protein tenascin X, a large extracellular matrix glycoprotein that interacts with collagens. Finally, there is a small set that has mutations that do not alter the triplet structure of type I collagen proteins but introduce usually disallowed amino acids in the sequence. These different groups are described separately, although for most the clinical descriptions are not as robust as for the others and distinguishing features are not always clear.

The most common form of dominantly inherited, or sporadic, classic EDS results from mutations in the type V collagen genes. The classical variety of EDS is usually inherited in an autosomal dominant fashion, although new mutations are common. Typically in the classical forms, the skin is soft and velvety in texture and can be extended several centimeters away from attachment sites (Figure 154-1). The skin has increased compliance but returns to its original shape promptly and is not usually lax. It is fragile, and there is easy bruising. Trauma results in gaping wounds that may bleed very little but heal with atrophic “cigarette-paper” scars. Areas of repeated trauma, such as elbows, knees, and shins, often have marked pigment deposition in addition to the characteristic scars. Small accumulations of connective tissue, “molluscoid pseudotumors,” may form in the skin and may be calcified.

Although it was initially reported that as many as 50% of infants with classical forms of EDS are born prematurely by 4–8 weeks (22), this claim was based on a relatively small study. Although there are no recent series in which this issue has been examined critically, clinical experience suggests that prematurity is less common than once thought. Bruising during the newborn period is unusual and most often begins as children start to crawl and stand. At this time, skin fragility also becomes evident, and characteristic scars may appear on the

**FIGURE 154-1** Clinical features of classical EDS (EDS type I). (A) Joint hypermobility, (B and C) “cigarette paper” scars and hyperpigmentation, and (D) skin hyperextensibility.

forehead, under the chin, and on the knees and elbows. Motor development may be slower than normal because joint hypermobility limits stability until muscle strength is sufficient to overcome ligamentous laxity. Intellectual development is normal in the absence of other complicating conditions.

There are no studies available to examine longevity of individuals with classical forms of EDS. The clinical impression is that life span is normal and not compromised by the condition. It has been estimated that up to half the people with classical EDS may have mitral valve prolapse, again on the basis of clinical experience, but few supporting data are available. A recent study of aortic diameter in individuals with classical and hypermobile EDS suggested that those individuals had aortic root and proximal aortic diameters that were distributed asymmetrically with more clustered toward the upper normal ranges. None of the adults in the group had diameters that appeared to put them out of the normal range but several individuals were excluded from the study because of ascertainment through aortic surgery (23). The frequency of surgery appears low, but one individual with classical EDS and a defined mutation in *COL5A1* was known to have had cardiac surgery (24) during adolescence. Other cardiac structural abnormalities are also

seen but the frequency is uncertain as this group of patients was recruited in a cardiac clinic (25).

Pes planus is common and moderate scoliosis is seen in some individuals. Ligamentous laxity appears to be associated with earlier than usual degenerative arthritis, although an underlying biochemical defect common to the ligament and cartilage has not been excluded.

**154.4.1.1 Other Forms of Classical Types of Ehlers–Danlos Syndrome.** There is a rare form of EDS that appears similar in initial presentation to the classical forms but is recessively inherited and may be accompanied by aortic dilation and cardiac valvular involvement (26–28). Individuals with this condition may have joint hypermobility and skin hyperextensibility but bruising is generally not striking. Aortic dilatation is a common feature in the older affected individuals and multiple valvular insufficiency can be seen. This group of individuals is distinguished from those with classical EDS by the underlying mechanism of disease, in that all have been found to be homozygous or compound heterozygotes for mutations that inactivate the *COL1A2* gene of type I collagen. The characteristic abnormalities in collagen fibril structure (see later discussion) are not seen.

An additional distinguishable group of individuals with a form of classical EDS is characterized by joint

hypermobility, skin hyperextensibility, and easy bruising, but they do not form abnormal scars (in contrast to both previous groups) (10,29,30). Mitral valve disease may be more common in this group than in other forms of classical EDS. In contrast to the most common classical form, this condition is inherited in an autosomal recessive fashion and the underlying mutations are in the *TNX* gene. One striking finding is that heterozygotes, particularly women, are likely to have significant joint hypermobility (31).

### 154.4.2 Biochemical and Molecular Genetic Bases of Classic Ehlers–Danlos Syndrome

**154.4.2.1 Type V Collagen Genes.** In the majority of individuals with classical forms of EDS, the underlying mutations are in the type V collagen genes, *COL5A1* and *COL5A2* (24,32–34). The pathway to this discovery was unexpectedly long. It has been known for many years that collagen fibrils in the dermis of individuals with classical EDS are 10–40% larger than normal (35–37), are irregular in outline, and “composite” structures are common (Figure 154-2). These altered fibrils, which consist largely of type I collagen, generally do not reflect alterations in type I collagen genes as linkage studies excluded them in some families (38–40). In the more common forms of classical EDS, biochemical studies of collagens synthesized by cultured fibroblasts were largely unhelpful (24,32,34) but linkage studies (41–43) served to strongly implicate type V genes in molecular pathogenesis. Segregation studies and direct mutation analyses make it clear that mutations in two type V collagen genes (*COL5A1* and *COL5A2*) do not underlie the clinical phenotype in, perhaps, a third of individuals with classical EDS (32,44), although problems in definitive ascertainment of phenotype could give similar results.

The identification of mutations provided the definitive demonstration of the role of these collagens in the clinical picture of classical EDS (44–48). The initially identified point mutation in the *COL5A2* gene was not published as a complete description for several years (49). The demonstration of mutations in the *COL5A1* (50a) gene began with identification of a chromosomal translocation that interrupted the gene on chromosome 9 (48). A second mutation that resulted in loss of the amino acids encoded by exon 65 of the *COL5A1* gene was the consequence of a 4-bp deletion from the intron 65 donor site (44). In another family, compound heterozygosity for a mutation that results in substitution for a glycine within the triple helical domain of the  $\alpha 1(V)$  chain (G1489D, indicated with respect to the first coding amino acid of the prepro $\alpha$  chain rather than of the triple helix, which is the anchor point for the other mutations cited) and a substitution amino-terminal to the triple helix (G530S), raises the question of the basis of moderate intrafamilial variability in this disorder (51). The recent finding of homozygosity for the *COL5A1* G530S

**FIGURE 154-2** Electron micrograph of collagen fibrils in skin from an adult with classical EDS. The normal fibrils (inset) are round and about equidistant. The fibrils in skin from the affected individual are larger than the controls, have irregular borders, and in some instances are markedly irregular. (Courtesy of Dr Karen Holbrook, University of Florida.)

variant in two individuals with classical EDS raises the question of whether it, too, could cause the phenotype in homozygotes (51). Within the *COL5A2* gene, both splicing mutations (46) and alterations in the triple helical sequences (33,49) have been identified that appear to alter the post-translational modification of type V collagen molecules and presumably alter their secretion and interactions in the matrix. Within the *COL5A1* gene, the initial identification of mutations that would alter the amount of the product synthesized (45,48) suggested that both qualitative and quantitative effects on type V collagen production could result in similar phenotypes. Mutation searching among *COL5A1* and *COL5A2* transcripts proved to be frustrating and in only the minority of affected individuals could mutations be identified (44,46).

This apparent paradox may have two resolutions. First, it is clear that a significant proportion of individuals with classic EDS (20–30%) have mutations in the *COL5A1* gene that lead to marked instability of the mRNA expressed from that allele (24,32–34). In all cases, the mRNAs appear to undergo “nonsense-mediated decay” and are not present or present in very low abundance in the cytoplasm (52,53). Search for mutations in the mRNA/cDNA (where most studies were done) would

not identify abnormalities because of the instability of the mutation-bearing sequences. It is now clear as well that other genes harbor mutations that result in the phenotype.

**154.4.2.2 A Recessive Form of Classic Ehlers–Danlos Syndrome that Results from Mutations in the *TNXXB* Gene.** Homozygosity for null mutation in the *TNXXB* gene, which encodes tenascin-X, gives rise to a clinical picture that shares much with classical EDS (29). *TNXXB* and a pseudogene (*TNXXA*) flank the active *CYP21B* gene, homozygous loss of which results in 21-hydroxylase deficiency. The first patient identified came to clinical attention because of 21-hydroxylase deficiency and was noted to have clinical findings of the classical variety of EDS. Notably, the characteristic alterations of collagen fibril structure in skin, characteristic of the classical forms of EDS, were missing. Following the initial identification of this condition, several additional families and affected individuals have been found (30,54). The protein is secreted by matrix cells and appears to be related to the formation of the elastic fiber network (55). Although the same defect in mice recapitulates most of the human phenotype (56), the molecular pathogenesis of the clinical outcome remains uncertain. A rearrangement that inactivates the *TNXXB* gene is thought to be present in about 10% of the carriers of 21-hydroxylase deficiency in some populations (57). Heterozygosity for null alleles results in significant joint hypermobility (31), making it a candidate gene for the hypermobile form of EDS. At present, the frequency of classical EDS that is the result of homozygosity or compound heterozygosity for *TNXXB* null alleles is not known. Surprisingly, no missense mutations in the gene have yet been identified.

**154.4.2.3 A Recessive Form of Classic Ehlers–Danlos Syndrome due to Null Mutations in the *COL1A2* Gene.** As indicated previously in this chapter, rarely, mutations in the *COL1A2* gene appear to lead to a specific variant of a recessively inherited classical form of EDS, but only a few such individuals have been identified (26–28,58). Cultured dermal fibroblasts from these individuals synthesize type I procollagen that contains only pro $\alpha$ 1(I) chains. Mutations have now been characterized in four affected individuals and in each case the mutation leads to introduction of a premature termination codon in the mRNA encoded by both *COL1A2* alleles. As a consequence the mRNA is unstable and rapidly degraded so that no protein is encoded. In two of the four individuals, the mutations are homozygous and the parents are consanguineous. In the remaining two, the alleles have different mutations and no parental consanguinity was known. These mutations differ from those seen in a child with a form of osteogenesis imperfecta (OI) whose cells made only pro $\alpha$ 1(I) chains and homotrimers (59–61). In those cells, homozygosity for a 4-bp deletion in exon 52 of the *COL1A2* gene led to a frameshift and a change in the last 48 amino acids of the chain. The difference in the phenotype between these two sets of individuals has been puzzling and the explanation for the variance is not yet

clear. In the cells from the child with OI, the protein is very unstable and probably degraded by the proteasome, an effect that might alter the cellular protein metabolism.

**154.4.2.4 Substitutions for Non-Glycine Residues in the Triple Helical Domain of  $\alpha$ 1(I) Chains.** In two unrelated patients with classical EDS, a mutation in one *COL1A1* allele results in substitution of a conserved arginine in the triple helical domain by cysteine (R134C within the triple helical domain) (62). Cysteine is absent from the triple helical domain of the normal pro $\alpha$ 1(I) chain, but when present can link two altered pro $\alpha$ 1(I) chains in the same molecule or, if only a single altered chain is in the molecule, leave a free sulfhydryl group for interaction in the matrix. Several other substitutions of cysteine for arginine within the triple helical domain have been identified that do not appear to result in the classical EDS phenotype (unpublished data). In contrast, the R836C mutation was recently associated with Caffey disease (infantile cortical hyperostosis) in unrelated families (63). As these individuals get older, their bone disease goes into remission but they develop joint hypermobility and skin hyperextensibility.

Another candidate for mutations in classical EDS is the fibronectin gene, which is thought to be altered in function in a single family with a form of EDS similar to a mild classical form and previously classified as having EDS type X (64). A mutation has never been identified.

## 154.5 HYPERMOBILE TYPE (EDS TYPE III—FAMILIAL HYPERMOBILITY)

### 154.5.1 Clinical Aspects

The hypermobile type of EDS, familial hypermobility, is an autosomal dominant disorder with variable expression in which the major clinical features are large and small joint hypermobility (9). There is considerable variability in the clinical expression both within and among families. The skin is generally of normal character. The major clinical problem is marked joint laxity, which may be accompanied by recurrent joint dislocation. Joint discomfort is often out of proportion to the apparent signs of mobility and puzzling to both the physician and the affected individual (65,66). Surgical repair of dislocation may be helpful in some people but the pain may be very difficult to ameliorate without use of significant pain medications and an integrated approach to management.

### 154.5.2 Biochemical and Molecular Genetic Aspects

One of the most disappointing aspects of the study of individuals with hypermobility forms of EDS is the relative lack of progress toward identification of the underlying mechanisms of the disorder. Several considerations probably contribute to the paucity of findings. First is the relative scarcity of large families in which to use linkage studies to identify candidate regions. In part, this

probably reflects the dynamic nature of the disorder, in which hypermobility is much more apparent in childhood and adolescence than in older life. Thus the identification of affected older individuals in families depends on historical considerations rather than clinical signs. Second is the likely heterogeneity of the disorder and the difficulty in distinguishing subtypes by clinical presentation.

The ultrastructural findings in skin are similar to those in EDS types I and II (35,67). In one family, however, a mutation in the *COL3A1* gene (Gly637Ser, in reference to the first glycine of the triple helical domain) was found (68). It is not clear if this family has a mild form of the vascular form of EDS (EDS type IV), in which the major manifestations of arterial and bowel rupture are delayed to a later age (69,70).

The most significant finding with respect to the genetic basis was the recognition that individuals who are heterozygous for null mutations in the *TNX* gene have significant hypermobility, consistent with the diagnosis of the hypermobility type of EDS (31,71,72). Strikingly, in this group the frequency of hypermobility is far higher in women than in men, consistent with the clinical impression that women have greater underlying joint mobility than men. In those families in which heterozygotes were studied, variability of the clinical presentation was marked and mimicked that seen in some other families in which mutations in *TNX* were not identified, suggesting the gender modifies the clinical presentation and must be considered in family studies and in counseling.

## 154.6 VASCULAR, ECCHYMOTIC TYPE (EDS TYPE IV)

### 154.6.1 Clinical Aspects

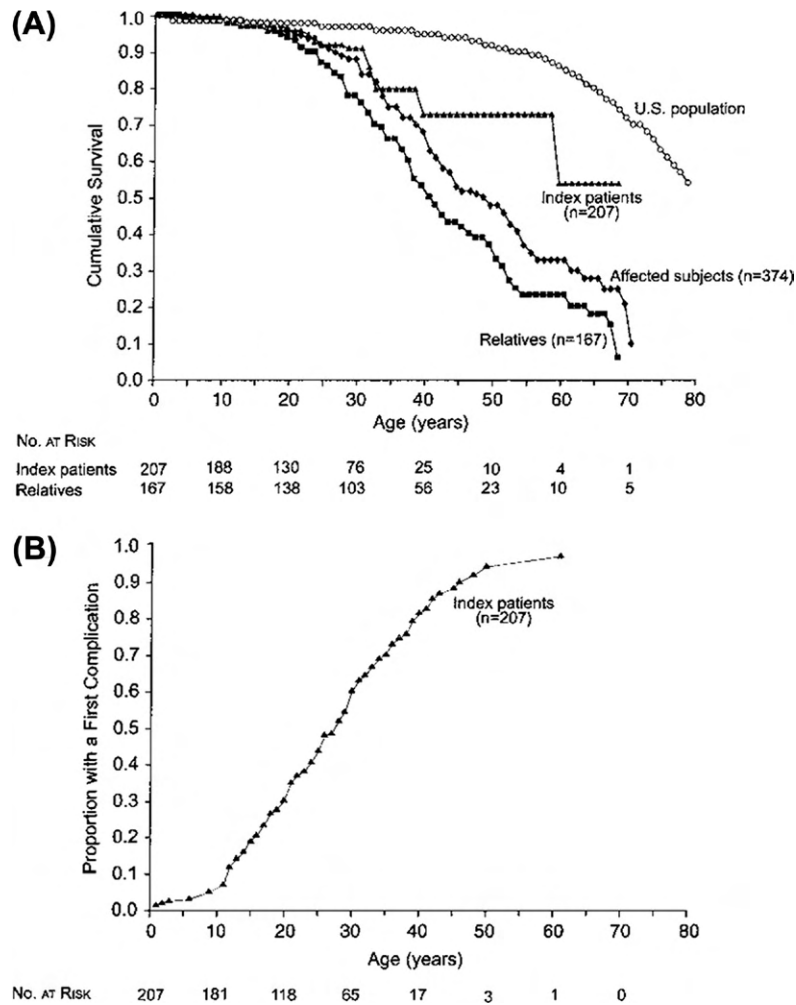

Ehlers–Danlos syndrome type IV, the vascular or ecchymotic variety, was recognized as a distinct entity by Barabas (46), although Sack (8) and Gottron (7a) had probably described the same condition. Many individuals with the vascular type of EDS have fragile, thin, or translucent skin through which the venous pattern is readily visible (Figure 154-3). They generally bruise easily and often have unexplained ecchymoses in well-protected areas. Some have a “characteristic” faces with tight skin, thin nose, and a “stare” (73,74) but, increasingly, as more individuals are identified by molecular genetic or biochemical studies, it is clear that clinical diagnosis on the basis of facial findings is not common. Large joint mobility is generally normal with hypermobility limited to the small joints of the hands. In those with the “acrogeric” form, the skin over the distal extremities has an aged, thin, and atrophic appearance (73,75,76). Venous varicosities are common and may be severe. In addition, congenital hip dislocation may be more common than expected (70), and keratoconus is a complication that may occur as early as 20 years of age (77) but can be treated successfully with corneal transplantation.

**FIGURE 154-3** Clinical features of the vascular type of EDS (EDS type IV). This 26-year-old woman's skin is thin so that the venous patterning shows readily over the chest. Her hands have a particularly aged appearance (acrogeria). She had a dissection of her right carotid artery in her late thirties without neurologic complications and died at age 48 years as a consequence of bowel rupture and sepsis.

The major clinical complications of the vascular type of EDS are arterial, bowel, and uterine rupture, emphasizing that although arterial complications are very common, other organs are involved as well. Because of these dramatic complications, life expectancy is shortened to a mean of less than 50 years for affected males and females (70) (Figure 154-4). This type of EDS is inherited in an autosomal dominant fashion. New mutations in the causative gene, *COL3A1*, are common and about one half of identified individuals with the condition have no apparent family history of the disorder. Although autosomal recessive inheritance was first thought to be the mode of inheritance (73,78) the supporting evidence was not strong and all the recent molecular genetic studies are consistent with heterozygosity for mutations in the *COL3A1* gene as the cause of the phenotype. There are no convincing examples of recessive inheritance for mutations in the *COL3A1* gene and similar phenotypes probably result from mutations in other genes (see, for example, Reference (79)).

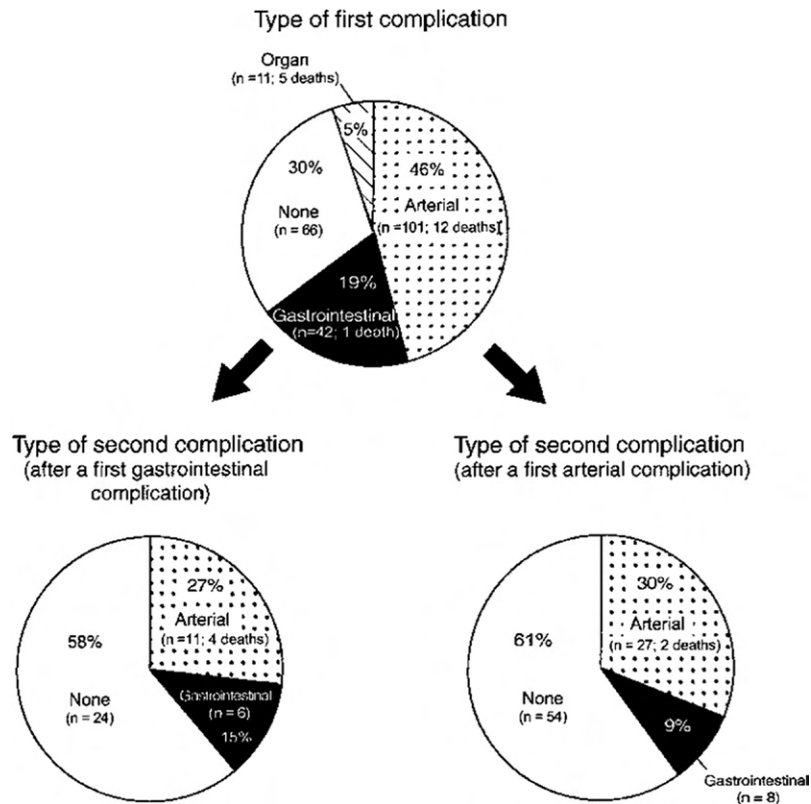

**FIGURE 154-4** (A) Survival curve and (B) age of penetrance with a major complication, for individuals with the vascular form of EDS. (From Pepin, M.; Schwarze, U.; Superti-Furga, A.; Byers, P.H. *Clinical and Genetic Features of Ehlers–Danlos Syndrome Type IV, the Vascular Type*. N. Engl. J. Med. **2000**, 342, 673–680.)

The most common complication is arterial rupture (70). The clinical presentation depends on the location of the ruptured artery. Hemorrhagic stroke (80), intrathoracic hemorrhage, intra-abdominal and retroperitoneal bleeding, and compartmental syndromes may all result (Figure 154-5). The cause of death in most individuals with EDS type IV is related to arterial bleeding. Bowel rupture, often rupture of the sigmoid colon, is the next most common complication of the disorder (70). Uterine rupture (70,81,82), as well as vascular rupture (83–86) and other vascular difficulties, which can include coronary artery dissection (87), may complicate pregnancy. These complications may be fatal and it appears that as many as 10% of woman who have one or more pregnancies may die of pregnancy-related complications (70).

The clinical features of the disorder are variable. In some individuals, the diagnosis can be made early in infancy because of the marked bruising and thin skin. In others, including some with a family history of the disorder, the diagnosis may be suspected in infancy because of bruising or, less commonly, some of the usual

complications. However, in many individuals the diagnosis is not suspected until a significant complication has occurred and even then, the vascular form of EDS might not be considered in the differential diagnosis. Major complications of the condition are uncommon in childhood, with less than 1% of affected individuals having identifiable events prior to puberty. About 25% have their first complication by age 20 and more than 80% have serious complications by 40 years of age (70). Despite this, there are individuals who live into their sixties and seventies.

The major cause of death is arterial rupture, accounting for more than 90% of deaths in men and a somewhat smaller proportion in women. Surgery is often complicated by the fragility of vessels, making repair difficult. Nonetheless, most people appear to survive the first episode of vascular rupture and that likelihood is increased if the diagnosis is known beforehand. Surgical intervention may be quite successful and lead to years extended life (88). One of the major controversies revolves around identification and treatment of aneurysms. Currently

**FIGURE 154-5** Distribution of complications among index cases with the vascular form of EDS and the outcome of those complications. (From Pepin, M.; Schwarze, U.; Superti-Furga, A.; Byers, P.H. *Clinical and Genetic Features of Ehlers–Danlos Syndrome Type IV, the Vascular Type*. N. Engl. J. Med. **2000**, 342, 673–680.)

there is no agreed-upon protocol by which to follow the vasculature in affected individuals. While molecular resonance or computerized tomographic imaging with contrast and three-dimensional reconstruction are very effective means to identify aneurysms, the friable nature of the vessels has made elective surgical intervention the less frequently followed option. In the past few years, the use of endovascular stents has encountered some success in apparently stabilizing aneurysmal regions of vessels (89–92) but failure is also encountered (93). This practice remains an unsettled question but clear evidence of success would be a welcome addition to the relatively limited armamentarium to be used in this setting.

Rupture of the bowel with sepsis accounts for only a small proportion of deaths in both men and women. As the major site of rupture is in the sigmoid colon (accounting for more than one third of the reported ruptures in our series), surgical removal of the distal colon has been used in an attempt to prevent additional episodes, apparently successfully in some individuals. Prompt surgical intervention is important, and the usual approach to bowel perforation is appropriate (94).

Other complications of EDS type IV include carotid cavernous sinus fistula formation (54a,54b,84a,91a,95a,96a,97a,98a), which has been treated successfully by embolization and arterial surgery.

There is currently no medical treatment known to decrease the risk of complications or to increase life span

predictably. There can be considerable variation in expression of a *COL3A1* mutation within the same family, making evaluation of therapies difficult. Surgical intervention, particularly for bowel rupture, may have a significantly beneficial effect (99). It is unclear whether removal of aneurysmal sections of major arteries is similarly helpful, as complications of surgery often ensue (100).

Although the vascular form of EDS is inherited in an autosomal dominant fashion and results from heterozygosity for mutations in the *COL3A1* gene, the recurrence rate following birth of an affected infant to unaffected parents is not zero (101–103). Recurrence results from parental mosaicism for the mutation, but at present the risk of recurrence is unknown. The rate of parental mosaicism could approach 15% (Schwarze, U. and Byers, P.H., unpublished). Prenatal identification of an affected fetus (or exclusion of the diagnosis) is possible by analysis of intragenic *COL3A1* markers in familial forms (12), by analysis of type III procollagen synthesized by cultured CVS cells (104), or by direct DNA analysis in families in which the mutation has been identified.

### 154.6.2 Biochemical and Molecular Genetic Aspects

The biochemical basis of this disorder, alterations in the synthesis and secretion of type III procollagen, was recognized in 1975 (78). The clinical diagnosis of EDS type

IV is generally suspected in the presence of marked bruising or following a major arterial or bowel complication in a young person, if there is no family history of the condition. The diagnosis can be confirmed biochemically by the demonstration of decreased type III procollagen production by cultured dermal fibroblasts. When examined by electron microscopy, skin from individuals with EDS type IV has characteristics that appear to depend on the nature of the mutation (21,35,37). With some mutations there is very marked intracellular storage of the abnormal type III procollagen with pooling of the material in the rough endoplasmic reticulum (Figure 154-6). In those individuals, collagen fibrils tend to be small and uniform in diameter. In others, intracellular pooling of procollagen appears to decrease, and fibril diameter becomes more variable.

More than 200 mutations in the *COL3A1* gene have now been identified in individuals with the vascular form of EDS (summarized in the Database of Type I and Type III Collagen Mutations—<http://www.le.ac.uk/genetics/collagen/>; (105,106)). Approximately two thirds of the mutations are single nucleotide substitutions that result in substitutions for glycine residues in the triple helical domain of the  $\alpha 1(\text{III})$  chain. Most of the rest are splice site mutations that result in exon-skipping, although some have more complex outcomes (107,108). Most mutations in the *COL3A1* gene that produce the vascular EDS phenotype are private to the family. There are two notable exceptions, both of which occur at CpG dinucleotides. The first results in substitution of serine for glycine at position 16 of the triple helix (Gly16Ser) and has been seen more than a dozen individuals (70). The second results in a mutation at the splice donor site of intron 24 and results in skipping of exon 24; this mutation has been seen in almost two dozen unrelated families (70). There are a small number of other mutations that have been seen in more than one family. There are a small number of multi-exon deletions (102,109,110) and some small genomic deletions that remove a portion of an exon (70,111).

The substitutions for glycine in the triple helix are not seen in the proportion expected (112) on the basis of glycine codon usage in the *COL3A1* gene. The small substituting residue alanine is seen far less often than predicted. It is possible that this low frequency could be related to a less severe phenotype that escapes clinical detection, or less effect on the protein folding that leads to less dramatic abnormalities in biochemical studies. Perhaps as direct genetic testing increases in frequency and the clinical range in which testing is used, this discrepancy may be explained by identification of a milder phenotype in which substitutions of glycine by alanine are found more frequently.

To date, *COL3A1* mutations that result in loss of a stable transcript are also seen far less frequently than anticipated based on mutation frequency in other collagen genes. For example, the mild osteogenesis

**FIGURE 154-6** Electron micrograph of fibroblasts in skin from patient depicted in Figure 154-3. The rough endoplasmic reticulum of each fibroblast in the field is markedly dilated (arrows) and filled with abnormal type III procollagen molecules. This patient is heterozygous for a point mutation in the *COL3A1* gene that results in substitution of the glycine at position 1018 in the triple helix by valine. (Micrograph courtesy of Dr Karen Holbrook.)

imperfecta (OI) type I phenotype almost always results from null mutations in the *COL1A1* gene and leads to half the normal production of type I procollagen. To date, only a handful of null mutations in the *COL3A1* gene have been identified (113), and although the phenotype is milder in some families there are others in which the clinical presentation is indistinguishable from that seen with other classes of mutation. As direct gene testing expands, it is likely that this group will be identified more often.

## 154.7 KYPHYOSCOLIOTIC EHLERS–DANLOS SYNDROME (EDS TYPE VI)

### 154.7.1 Clinical Aspects

The kyphoscoliotic type of EDS (EDS type VI) was the first true molecular disorder of collagen metabolism to be recognized in humans (98). The first patients described were two sisters who had smooth, hyperextensible, velvety skin; moderate scarring; bruising; large and small joint laxity; a marfanoid habitus with moderately severe thoracic kyphoscoliosis; and keratoconus with ocular globe fragility (Figure 154-7). Since the original report, more than 20 individuals with EDS type VI have been described (57a,92a,96,114,115,116,116a,116b,117–122). Many of these reports are linked

**FIGURE 154-7** Clinical features of the oculo-scliotic type of Ehlers–Danlos syndrome (EDS type VI). The young girl in the photograph is one of the first children recognized to have this condition. She has a marfanoid habitus and scoliosis and ruptured her ocular globe following minor trauma. (Courtesy of Dr Sheldon Pinnell, Duke University.)

to mutation analysis and, unfortunately, there has been no attempt to define a natural history of the disorder from all the available patients. The major clinical clue to early diagnosis is profound hypotonia in the newborn period and progressive scoliosis. It is not uncommon for children with this form of EDS to be evaluated for neurological disorders before the diagnosis of EDS is reached.

The disorder is inherited in an autosomal recessive fashion. It is not clear if there is an ethnic or racial predisposition, although from the reported patients almost all are of white background. The frequency of the kyphoscoliotic type of EDS is not known. In a recent survey of allele frequency, the most common allele—a 7-exon duplication involving exons 10–16—was found in 1 of 582 normals studied (121). This allele, which appears to represent a single mutational event, accounts for about half of the mutant alleles so far identified in affected individuals (119) but about 20% of all mutant alleles (123). If these represent approximate frequencies, then the kyphoscoliotic form of EDS could affect as many as 1 in 60,000 individuals. This frequency seems much higher than that recognized at present, so the estimate could be biased by the population assayed for the common mutation.

In two compilations of the clinical features of reported individuals (2,118,124) identified through biochemical screening, it was striking that vascular complications, including intracerebral and other arterial hemorrhage, were more common than had been anticipated and contributed to morbidity in at least three individuals. If scoliosis is severe, cardiopulmonary compromise can shorten lifetime (125).

As with other recessively inherited disorders, the recurrence risk for an additional affected sibling, following the birth of a child with the type of EDS, is 25%. Prenatal identification of an affected fetus or exclusion of the disorder can be accomplished by direct mutation detection in appropriate families (120), or by measurement of enzymatic activity in cultured amniocytes or chorionic villus cells (126).

Treatment with ascorbic acid in some individuals enhances lysyl hydroxylation in collagens as measured by excretion of hydroxylysine in the urine (127) and may ameliorate the clinical phenotype over a period of several months. Ascorbate appears to act by inducing the enzyme and by acting as a cofactor (114,127–129).

Treatment of scoliosis with bracing appears to be unsuccessful, and even with surgery the outcome apparently is uncertain. Ocular globe fragility can lead to loss of vision although surgical techniques are being proposed that may preserve vision (130).

A small number of individuals with phenotypic features that appear compatible with the clinical diagnosis of the oculo-scliotic type of EDS do not have evidence of biochemical abnormalities in the enzyme (2,20), and this is referred to as the type B form of the syndrome. The molecular and biochemical basis of this condition is uncertain.

### 154.7.2 Biochemical and Molecular Genetic Aspects

The kyphoscoliotic form of EDS (EDS type VI) results from mutations in the *PLOD1* gene (119) that encodes the enzyme lysyl hydroxylase 1, which hydroxylates triple helical lysyl residues in collagens. The *PLOD1* gene is located at chromosome 1p36.2–p36.3 (131). Two other lysyl hydroxylases, *PLOD2* and *PLOD3*, have been identified (132) but all the mutations known to produce the kyphoscoliotic form of EDS are in the *PLOD1* gene (Table 154-2). This enzyme does not appear to hydroxylate the lysyl residues in the telopeptide regions (just external to both ends of the triple helix) (103a). Modification of the telopeptide lysyl residues involved in cross-link formation appears to be the domain of the *PLOD2* gene (133). Mutations in that gene result in Bruch syndrome, a form of osteogenesis imperfecta with joint contracture (133,134). Mutations in *PLOD1* decrease the activity of the enzyme to about 10% or less of the normal level, leading to decreased lysyl hydroxylation within the triple helical domains of

type I and III collagens. Type II collagen appears to be normally hydroxylated, presumably because one of the other enzymes is expressed with greater abundance in that tissue. The consequence of decreased lysyl hydroxylation is altered production of the stable intermolecular cross-links that provide tissues with tensile strength (114a). Although alterations in enzymatic activity are readily demonstrated in cultured dermal fibroblasts, the assay is cumbersome and not performed in many places. The alteration in the collagen cross-links produced is reflected in the altered ratio of hydroxylated to unhydroxylated cross-links excreted in the urine, providing a relatively simple, rapid, and inexpensive diagnostic test for the condition (135,136).

As indicated above, the most common mutant allele of the *PLOD1* gene is a duplication of approximately 8.9kb of the gene that contains seven exons (9,13,29,55,83,100,137) as a result of Alu–Alu recombination (115,117,123). Analysis of linked polymorphic variants in the mutant allele suggests that the majority of the alleles are the progeny of a single mutational event (119,123); an alternate but less likely possibility is that the alleles identified by the variants contain a predisposing sequence and, so, the mutation has occurred several times. The duplication involved Alu elements located in introns 9 and 16 (117). The mutation results in an in-frame duplication of 260 amino acid residues. The mRNA appears to be stable

but the enzyme is nonfunctional. Of 53 known mutant alleles compiled in 2000 (119), 27 are represented by the duplication allele. This frequency clearly represents a bias of ascertainment as the allele can be readily recognized and thus tested for. One other allele, 1557C>G (Y511X), has been found in 7 alleles, and two others (see Table 154-2) have been identified in more than one individual. The remaining 11 mutant alleles have been seen in single individuals. In the majority of individuals in which the duplication has been identified, the second allele has not yet been described.

The mutations include those in which premature termination codons lead to very unstable mRNA (see Table 154-2) and others in which the mRNA appears to be stable but the resulting protein lacks enzymatic activity. There does not appear to be a recognizable phenotype–genotype correlation at this point.

## 154.8 ARTHROCHALASIS TYPES OF EHLERS–DANLOS SYNDROME (EDS TYPES VIIA AND VIIB)

### 154.8.1 Clinical Aspects

The former EDS type VII has now been divided into two groups—one referred to as the arthrochalasis types and the other as dermatosparaxis (see later discussion) (9). Arthrochalasis refers to very marked joint laxity

<sup>a</sup>The nucleotide number of the mutation is in reference to the A of the initiator methionine residue in the coding sequence. This differs from the sequence of the cDNA (GenBank M98252) in which the cDNA sequence has an additional 24 nucleotides. Many of the mutations in the literature have used the GenBank sequence as the basis of the description so the nucleotide numbers here may be 24 less than those cited but the amino acid numbering remains as before in which the initiator methionine is residue 1 of the sequence.

characteristic of two groups of EDS (the former types VIIA and VIIB) but, unfortunately, is not a term in general use in the medical community, although the term arthrochalasis multiplex congenita is used in the orthopedic literature. It is likely that only a small group of individuals identified in that literature actually have the molecular defects that define this type of EDS.

Ehlers–Danlos syndrome types VIIA and B (used here for clarity) are characterized by marked joint laxity, bilateral congenital hip dislocation, and relatively normal skin (Figure 154-8) (21,138,139). The hip dislocation may be recalcitrant to routine therapy and even to surgical repair. Short stature is seen in some, and some individuals have mild midface hypoplasia and a small nasal bridge. Wormian bones in the skull and long bone fractures have been seen some individuals with both forms (Table 154-3). There is a surprising degree of heterogeneity such that some individuals have lifelong difficulties with joint mobility that limit their ability to ambulate, while others do well following surgery to stabilize their hips.

Although the majority of reported individuals are the first affected in their family, biochemical and molecular genetic studies (see later discussion) confirm that the disorder results from heterozygosity for mutations in the *COL1A1* and *COL1A2* genes of type I collagen. The majority of affected individuals represent new mutations, but the small number of families in which the disorder is inherited through multiple generations confirms the nature of inheritance (138,140).

### 154.8.2 Biochemical and Molecular Genetic Aspects

When EDS type VII was first distinguished from other forms of EDS (141), the condition was thought to be due to alteration in the enzymatic processing at the N-terminal end of the type I procollagen molecule, analogous to

the, then recently identified, disorder dermatosparaxis in cattle (141a). It was subsequently shown (142) that there was a defect in the structure of type I procollagen molecules, synthesized by cells cultured from some of the same affected individuals. It soon became clear that mutations at the splice donor and splice acceptor sites of exon 6 of the *COL1A1* and *COL1A2* genes, or deletion of the exon itself, result in the phenotypes (Figure 154-9; see also Table 154-3) (21,108,143–153). In general, mutations in the *COL1A1* gene give rise to more striking joint laxity, although it is unlikely that the clinical features alone would distinguish disorders in the two genes.

Exon 6 of both genes contains the N-proteinase site as well as a lysine residue that is hydroxylated and involved in cross-link formation. Mutations in the splice donor site of both genes result in skipping exon 6. As a consequence, chains that lack the sequences encoded by exon 6 cannot be cleaved by the normal proteinase and molecules contain one or more abnormal pro $\alpha$ 1(I)-chains or an abnormal pro $\alpha$ 2(I) chain (see Figure 154-9). Mutations at the splice acceptor site have slightly different effects that appear to depend on the nature of the substituting nucleotide and its position. At positions 14 and 15 of each exon, there is an AG dinucleotide that can serve as a splice acceptor site if the constitutive site is lost. As a result, with some splice acceptor mutations the cryptic site is often used, which results in deletion of 15 nt from the mature mRNA. These nucleotides encode the first five amino acid residues of the exon, which includes the N-proteinase site. The lysine residue involved in cross-link formation is lost if the entire exon is deleted. In both instances, the formation of collagen fibrils is disturbed (150,154). The effect of these mutations on bone integrity (i.e. the occasional fracture and wormian bones seen in some individuals) may reflect interference with mineralization of collagen fibrils by the retention of the propeptide in bone.

**FIGURE 154-8** Clinical features of arthrochalasis multiplex congenita (EDS type VIIA). This infant was born with bilateral congenital hip dislocation and had marked joint laxity as well as a large inguinal hernia. This child has a *COL1A1* acceptor splice site mutation. (Courtesy of Dr Louanne Hudgins, Stanford University.)

## 154.9 DERMATOSPAXIS (EDS TYPE VIIC)

### 154.9.1 Clinical Aspects

Dermatosparaxis, EDS type VIIC, is a recessively inherited disorder that results from absence of the activity of procollagen N-proteinase (now known as *ADAMTS2*) (155), the enzyme that cleaves the N-terminal propeptide from type I procollagen. About a dozen children with this disorder have now been identified (155–162). Affected children all exhibit striking joint laxity; extremely soft, fragile, and extensible skin; easy bruising; mild hirsutism; a small chin; and blue sclera (Figure 154-10). One child was noted to have inguinal tears at birth (160,162) and one was born prematurely (156). One of the first children reported (162) had a perinatal cerebral hemorrhage but was intellectually normal at age 2. The oldest

of the known affected individuals is now in her early twenties (161). At age 16 she had normal intellect, and very marked wrinkling and redundancy of the skin over her hands and feet, and of the skin of her face. No other major complications had ensued although joint laxity, easy bruising, and skin fragility persist.

The activation of residual enzyme, if present, or replacement of enzymatic activity would be the most beneficial treatment. There is no consensus on therapy at this point, and because the natural history is not yet well defined, the objectives of therapy are not well delineated. The natural history of dermatosparaxis in animals is not well studied although the disease is known in several species (163–167). It remains to be determined if the vascular wall is well maintained even when skin is dramatically altered. Such studies could be helpful in planning therapeutic intervention.

### 154.9.2 Biochemical and Molecular Genetic Aspects

Cultured dermal fibroblasts from children with dermatosparaxis fail to remove the amino-terminal propeptide from type I procollagen (159,162). In skin from affected individuals there is a small amount of conversion, but

it is not clear if the site used is the normal cleavage site (162). Collagen fibrils in skin from these children have a unique “hieroglyphic” pattern when viewed in cross-section and appear ribbon-like in longitudinal section (Figure 154-11). The altered packing is a consequence of failure to remove the N-terminal propeptide (168). This condition was known in cattle, sheep, dogs, and cats for many years before the human variant was identified. In cattle and humans it is clear that mutations in the gene that encode the procollagen I N-proteinase are responsible for the phenotype (156). Five of the six children who were first identified were homozygous for the same mutation that resulted in a premature termination codon (Q225X). Three of these children were from Ashkenazi Jewish families, although there was no known consanguinity in the families. A fourth was of Hispanic origin and the fifth of undefined white background. Four of the five were homozygous at three polymorphic sites downstream from the mutation while the fifth was heterozygous at one of the sites. We found no examples of the allele in 192 Ashkenazi chromosomes (Schwarze, U. and Byers, P.H., unpublished). The sixth child was born to first cousins and was homozygous for a different mutation, W795X. In both instances the major product of the gene appeared to be very unstable, consistent with

**FIGURE 154-9** Mutations in the *COL1A1* and *COL1A2* genes that result in the EDS type VIIA and EDS type VIIB phenotypes, respectively. The mutation in each instance is underlined, and the effect of the mutation on mRNA splicing is shown (dashed lines). The bibliographic citations to the left indicate the origin of the data for the mutations.

nonsense-mediated decay of the mRNA. Subsequent analysis has identified a series of other mutations that may not destabilize the mRNA, as would be expected for premature termination codons in central exons (155).

With a known mutation, prenatal diagnosis is feasible and can be used to exclude or confirm the diagnosis in subsequent pregnancies.

The bovine mutation is a 17-bp deletion that results in a frameshift and premature termination codon. The mutations have not been identified in the other animals with the condition.

## 154.10 OTHER FORMS OF EHLERS–DANLOS SYNDROME

### 154.10.1 X-linked Ehlers–Danlos Syndrome (EDS Type V)

Beighton (1,3) described a family in which affected males had skin hyperextensibility similar to that seen in EDS type II. Joint mobility and cutaneous bruising were thought to be less extensive, but intramuscular hemorrhage was more common. There was no evidence of

**FIGURE 154-10** Clinical features of human dermatosparaxis (EDS type VIIC). (A and B) A 15-year-old girl with very marked wrinkling of the skin of her face and hands. (From Reardon, W.; Winter, R.M.; Smith, L.T.; et al. *The Natural History of Human Dermatosparaxis (Ehlers–Danlos Syndrome Type VIIC)*. Clin. Dysmorphol. **1995**, 4, 1–11.)

abnormalities in lysyl oxidase function or in collagen cross-link formation (169), as have been found in cells cultured from individuals with occipital horn syndrome (170). Linkage to the Xg blood group and color blindness were excluded in the family (171). It is unclear whether this family, instead, has an autosomal dominant form of EDS, probably a variety of the classical form, with variable expression. Until additional linkage studies can demonstrate an X-chromosomal location for this disorder, the uniqueness of the condition remains uncertain.

### 154.10.2 Periodontal Form of Ehlers–Danlos Syndrome (EDS Type VIII)

The periodontal form of EDS was first proposed as a separate entity on the basis of two families in which periodontal disease was accompanied by marked bruising, joint hypermobility, and skin hyperextensibility (172). The

condition was inherited in an autosomal dominant fashion. In those families, affected individuals had lost most of their teeth by their early twenties as a result of gingival recession that did not appear to be primarily inflammatory. A small number of additional families have been described (97,137,173–177). Pretibial bruising is often more pronounced than expected with other forms of EDS.

Biochemical studies have failed to identify abnormalities in type I or III procollagen (174,175). The condition should be distinguished from EDS type IV, in which periodontal disease is common. The treatment of the noninflammatory gingival recession is not clear but assiduous attention to dental hygiene may be helpful. Orthodontic manipulation may lead to early loss of teeth (97). Gene mapping studies now suggest that EDS type VIII, the periodontal type, may be genetically heterogenous. One locus was mapped to a 4.5 Mb region on the short arm of chromosome 12, but analysis of several candidate genes in the region was not fruitful. On the basis of those studies, there appears to be at least one additional locus and perhaps more.

### 154.10.3 Fibronectin Defect Form of Ehlers–Danlos Syndrome (EDS Type X)

This disorder was described in a single family, in which mild features compatible with EDS type II or III were associated with a variable disorder of platelet aggregation that could be corrected with heterologous plasma or purified fibronectin (64). Skin from one affected individual had alterations in fibril morphology. No biochemical defect in fibronectin has yet been identified. In as much as platelet aggregation defects may be a concomitant finding in some individuals with different forms of EDS (178), it is unclear that this condition warrants a unique identity.

### 154.10.4 Progeroid Type of Ehlers–Danlos Syndrome

Several children have now been described with progeroid facies, multiple nevi, mild mental retardation, skin hyperextensibility, bruisability, moderate skin fragility, and joint hypermobility principally in digits, with radio-ulnar synostosis and developmental delay (179,180). There is moderate variation in the clinical presentation. Inheritance is autosomal recessive and mutations have been identified in the *B4GALT7* gene that encodes galactosyl-transferase-I (179,181,182). The enzyme is responsible for the transfer of galactose to the xylose residue on serines in the formation of heparin sulfate and chondroitin sulfate.

### 154.10.5 Ehlers–Danlos Syndrome with Periventricular Heterotopia

Two reports from 2005 describe an X-linked dominant disorder, with probably male lethality, characterized

**FIGURE 154-11** Electron micrograph of skin from individuals with EDS type VIIA, EDS type VIIB, and dermatosparaxis. Collagen fibrils in normal skin have a uniform diameter and regular spacing (A). In skin from patients with EDS type VIIB (B) and EDS type VIIA (C) there is increasing irregularity of the fibrils, while the skin from a child with dermatosparaxis has very disorganized fibrils (D). (From Byers, P.H.; Duvic, M.; Atkinson, M.; et al. *Ehlers–Danlos Syndrome Type VIIA and VIIB Result from Splice-Junction Mutations or Genomic Deletions that Involve Exon 6 in the COL1A1 and COL1A2 Genes of Type I Collagen*. *Am. J. Med. Genet.* **1997**, 72, 94–105.)

by joint hypermobility, skin extensibility but without significant scarring, presentation with seizures, and the radiological finding of brain heterotopia, often in the periventricular region (7,183). Some of the individuals had arterial aneurysms, including aortic enlargement. Two similar patients had been reported previously (184,185). Surprisingly, the mutations in the families were found in the *FLNA* gene that encodes the protein filamin A, a protein that cross-links the actin fiber cytoplasmic network in cells. Mutations in the gene are known to cause otopalatodigital syndrome types 1 and 2, frontometaphyseal dysplasia, and Melnick–Needles syndrome. The clinical differences are no doubt related to specific mutations in the gene.

### 154.11 SUMMARY

Some forms of EDS are common, while others are rare. It is important to identify those individuals with EDS type IV because they are at risk of significant medical complications. In addition, it is important to identify those with EDS type VI because the genetic risk in the families is different than it is for those with the far more common dominantly inherited forms. Many individuals have some of the clinical features of EDS, including joint laxity and soft extensible skin, yet do not fit clearly into the major categories of EDS. Further biochemical and molecular genetic studies of such individuals and families will be important to identify the underlying molecular defects and the natural history of the disorders.

## Heritable Diseases Affecting the Elastic Fibers: Cutis Laxa, Pseudoxanthoma Elasticum, and Related Disorders

Jouni Uitto

Department of Dermatology and Cutaneous Biology, Jefferson Medical College, Philadelphia, PA, USA

This article is a revision of the previous edition article by Jouni Uitto and Franziska Ringpfeil, volume 3, pp 3647–6370, © 2007, Elsevier Ltd.

### 155.1 INTRODUCTION

The elastic fiber system of connective tissues forms a network that is responsible for resilience and elasticity of various organs. The relative concentration and distribution of elastic fibers in different tissues varies (Table 155-1). Their relative concentration is highest in the aorta and arterial blood vessels as well as in the lungs, while lower concentrations are present in the skin and various tendons. An important specialized tissue location of the elastic structures is Bruch's membrane, an elastin-rich sheath in the eye within the retina. Elastin is synthesized in arterial tissues by vascular smooth muscle cells, and the likely cell type responsible for elastin synthesis in the skin is the fibroblast (Figure 155-1A).

Examination of the elastic connective tissues in human dermis reveals an interconnecting fiber structure consisting of an intricate network of fibers of varying diameters (Figures 155-1B, C, and 155-2A). Transmission electron microscopy reveals that mature elastic fibers consist of two distinct components, elastin, a well-characterized connective tissue protein, and elastin-associated microfibrils (1,2) (Figure 155-2B). In mature connective tissue, elastin forms the core of the fiber while the microfibrils are relatively minor components at the periphery of the fibers. However, in elastin fibrillogenesis during fetal development or during elastic fiber regeneration, the first components being synthesized are the microfibrils, which form a scaffold in which the elastin molecules align. With increasing fetal age and maturation of the elastic fibers, elastin becomes the predominant component.

In fact, electron microscopic estimations of the fully matured elastic fibers suggest that the elastin protein represents over 90% of the total content of the fibers. Thus, the microfibrils appear to play a critical role during early fibrillogenesis, while the physiologic properties of mature elastic fibers are primarily attributable to the elastin network. It should also be noted that microfibrils devoid of elastin can be identified in a number of tissues (see also Chapter 153). These microfibrils may consist of some of the same components as noted in association with elastic fibers, as for example the fibrillins and the fibulins, or they may be composed of unrelated proteins, such as type VI collagen.

**TABLE 155-1** Relative Concentrations of Elastin and Collagen in Various Tissues<sup>a</sup>

Tissue	Percentage of Dry Weight	
	Elastin	Collagen
Skin	0.6–2.1	71.9
Lung	3–7	10
Aorta	28–32	12–24
Ligamentum nuchae	74.8	17
Achilles tendon	4.4	86.0
Liver	0.16–0.30	3.9

<sup>a</sup>The values represent determinations from different animal species; the tissue origin and the assay methods are described in Grant, M. E.; Prockop, D. J. The Biosynthesis of Collagen. *N. Engl. J. Med.* **1972**, *286*, 194–199; 242–249; 291–300.

The biochemical characterization of elastin and associated microfibrillar proteins was hampered for many years by their insolubility. However, with the advent of techniques of molecular biology, many of the structural components of elastic fibers are now well characterized, and critical features of their basic structure and expression of the corresponding genes are well known (1,3,4) (Table 155-2). Interest in understanding the elastic fiber network has recently increased with the realization that changes in the structure and metabolism of these fibers are associated with a number of heritable and acquired diseases (Table 155-3).

## 155.2 BIOLOGY OF ELASTIN

### 155.2.1 Protein Structure

The basic molecular unit of elastin is a linear polypeptide, also known as tropoelastin, with an approximate molecular mass of 70 kDa. The precise amino acid sequence of human tropoelastin was originally deciphered from cloning of full-length cDNA and the corresponding gene (*ELN*) (5,6) (Figure 155-3). Amino acid composition of elastin is rich in hydrophobic residues, and about one-third of the total number of amino acids is composed of glycine residues. The distribution of glycine is different, however, from that in collagen, where glycine occupies every third residue in a repeating Gly-X-Y sequence. Instead, in elastin the glycine residues are clustered within hydrophobic domains, which

alternate with alanine- and lysine-rich sequences, so-called cross-link domains (Figure 155-4). It is of interest to note that elastin also contains some hydroxyproline, but the relative content of this amino acid is considerably lower than in collagen and the values for hydroxyproline are variable.

One of the characteristic features of elastic fibers is the presence of cross-links, which render the individual tropoelastin molecules highly insoluble (see Figure 155-4). The two major cross-link compounds, known as desmosine and isodesmosine, are apparently unique to elastin (7). The content of desmosine in various elastin preparations has been shown to be fairly constant, ~1.5 residues per 1000 amino acids, and assay of these cross-links can therefore provide a quantitative measure of the elastin content in tissues (8).

The elastic fibers display a resilient nature, providing elasticity to various organs owing to the presence of alternating hydrophobic and cross-link domains. When stretched, the hydrophobic domains are exposed to the surrounding aqueous milieu, and the energy for contraction of the fibers is derived from return of these hydrophobic groups to the nonaqueous environment. Thus, alterations in the primary structure of tropoelastin, or in the cross-linking process, which is enzymatically mediated by lysyl oxidase (see later discussion), could perturb

**FIGURE 155-1** Ultrastructure of elastic fibers in human skin. (A) Transmission electron microscopy demonstrates a fibroblast (F) surrounded by elastic sheets (E) and collagen fibers (C). (B and C) Scanning electron microscopy reveals the presence of interconnecting fibers of variable diameters. (Modified from Uitto, J.; Rosenbloom, J. *Elastic Fibers*. In *Dermatology in General Medicine*; 5th edn; Freedberg, I. M., Eisen, A. Z., Wolff, K., et al., Eds.; McGraw Hill: New York, 1999; p. 260.)

**FIGURE 155-2** Morphology of the elastic fibers in human dermis. (A) Elastic fibers, visualized by histopathology using an “elastin-specific” stain (Verhoeff–van Gieson), form an interconnecting network (black). (B) Transmission electron microscopy of an individual elastic fiber reveals the presence of an electron-lucent central core consisting of elastin, and electron-dense (darker) elastin-associated microfibrils, which are superimposed on the core.

**TABLE 155-2 Clinical Features, Histopathology, Inheritance, Associated Biochemical Findings, Gene Defects, and Predisposing Conditions in Diseases with Elastic Fiber Abnormalities**

Disease	Inheritance <sup>a</sup>	Clinical Manifestations	Histopathology of Elastic Fibers	Gene Defects, Biochemical Findings, and Predisposing Clinical Conditions
Pseudoxanthoma	AR, NH	Yellowish papules coalescing into plaques Inelastic skin Cardiovascular and ocular abnormalities	Accumulation of pleomorphic and calcified elastic fibers in the mid-dermis	Deposition of calcium apatite accumulation of glycosaminoglycans MRP6/ABCC6 gene mutation β-thalassemia; D-penicillamine treatment
Buschke–Ollendorff syndrome	AD	Dermatofibrosis lenticularis disseminata and osteopoikilosis	Accumulation of interlacing elastic fibers in the dermis	Increased desmosine content
Cutis laxa	AR, AD, or NH	Loose, sagging, inelastic skin Pulmonary emphysema Urinary and gastrointestinal tract diverticuli	Fragmentation and loss of elastic fibers	Decreased desmosine content; FBLN5 gene mutation increased elastase activity D-penicillamine treatment skin lesions (e.g. drug reaction)
Copper deficiency syndromes	XR	A spectrum of clinical manifestations—Menkes syndrome; Occipital horn syndrome (previously X-linked cutis laxa)	Paucity of the central amorphous component of elastic fibers while the microfibrillar material is normal. Frayed and split arterial intima reflecting defect in elastin and collagen cross-linking	Reduced activity of lysyl oxidase copper-dependent enzyme ATP7A gene
DeBary syndrome	AR	Cutis laxa-like skin changes Mental retardation Dwarfism	Rudimentary, fragmented elastic fibers	Reduced elastin mRNA levels
The wrinkly skin syndrome	AR	Decreased elastic recoil of the skin Increased palmar and plantar creases	Decreased number and length of elastic fibers	Variant of cutis laxa?
Mid-dermal elastolysis	NH	Fine wrinkling of the skin, primarily in exposed areas	Fragmentation and loss of elastic fibers in the mid-dermis	Sun exposure
Anetoderma	NH	Localized areas of atrophic, sac-like lesions	Loss and fragmentation of elastic fibers in the dermis	Reduced desmosine content due to inflammatory reactions
Elastosis perforans	NH	Hyperkeratotic papules, commonly on the face and neck	Accumulation and transepidermal elimination of elastic fibers	D-penicillamine-induced septal cross-linking
Elastoderma	Unknown	Loose and sagging skin with loss of recoil	Accumulation of pleomorphic elastotic material without calcification in the mid and lower dermis and the subcutaneous tissue	Variant of pseudoxanthoma

**TABLE 155-2 Clinical Features, Histopathology, Inheritance, Associated Biochemical Findings, Gene Defects, and Predisposing Clinical Conditions in Diseases with Elastic Fiber Abnormalities—Cont'd**

Disease	Inheritance <sup>a</sup>	Clinical Manifestations	Histopathology of Elastic Fibers	Gene Defects, Biochemical Findings, and Predisposing Clinical Conditions
Isolated elastomas	NH	Dermal papules or nodules	Accumulation of thick elastic fibers in dermis	
Elastofibroma	NH	Deep subcutaneous tumor, usually on subscapular area	Accumulation of globular elastic structures encased in collagenous meshwork	Trauma on the lesional area; chronic sun exposure
Actinic (solar) elastosis	NH	Thickening and furrowing of the skin	Accumulation of irregularly thickened elastic fibers in dermis	Chronic sun exposure
Marfan syndrome	AD	Skeletal, ocular, and cardiovascular abnormalities, hyperextensible skin; striae distensae	Fragmentation of the elastic structures in aorta	Mutations in the FBN1 gene
Congenital contractural arachnodactyly	AD	Joint contractures		Mutations in the FBN2 gene
Williams syndrome	AD	Supravalvular aortic stenosis; velvety skin; dysmorphic facies	Disruption of smooth muscle and matrix relationship affecting blood vessels	Allelic deletion of the elastin gene
Costello syndrome	Unknown	Multiple developmental defects; soft skin with excess wrinkling and deep creases on hands and feet	Impaired deposition of insoluble elastin in different tissues	Improper assembly of elastin; 67 kDa elastin-binding protein defect in fibroblasts
Variants of corneal dystrophy	AD, AR	Progressive opacification of the cornea leading to severe visual handicap	Progressive accumulation of corneal deposits (amyloid)	Mutations in the gene encoding the corneal protein

AD = autosomal dominant; AR = autosomal recessive; XR = X-linked recessive; NH = not a heritable disease.

<sup>a</sup>Most of these conditions represent a group of diseases with clinical, genetic, and biochemical heterogeneity.

<sup>b</sup>The genetic defects and biochemical abnormalities have been demonstrated in only a limited number of patients in each group, and it is not known whether they are the same in all patients. The biochemical findings listed are those related to elastic fibers.

<sup>c</sup>Most cases are AR or sporadic with unknown inheritance. Rare cases with a distinct acquired form of pseudoxanthoma elasticum have been described.

**TABLE 155-3 Components of Elastic Fibers**

Protein	Characteristic Features	Human Gene Locus
Elastin MICRO-FIBRILLAR PROTEINS	~68 kDa, several splice variants; insoluble, highly cross-linked; provides elasticity to tissues	7q11.2
<b>Fibrillins</b>	350 kDa	
FBN1	Contain EGF and TGF- $\beta$ -binding protein motifs	15q15–q21
FBN2	Contain EGF and TGF- $\beta$ -binding protein motifs	5q23–q31
<b>Latent TGF-<math>\beta</math> Binding Proteins (LTBP)</b>		
LTBP1	150–205 kDa	2p12–q22
LTBP2	Contain EGF and TGF- $\beta$ -binding protein motifs	14q24
LTBP3	Secreted as a complex with latent TGF- $\beta$ ; bone defects in null mice	11q12
<b>Fibulins</b>		
FBLN1	100–240 kDa	22q13.3
FBLN2	Contain EGF and anaphylatoxin motifs	3p24–p25
FBLN5		
<b>Microfibril-Associated Glycoproteins (MAGP)</b>		
MAGP1 (MFAP2)	31 kDa; widely distributed in microfibrils	1p36.1–p35
MAGP2 (MP25)	25 kDa	12p12.3–p13.1
<b>Microfibril-Associated Proteins</b>		
MFAP1	Very acidic	15q15–q21
MFAP3	Expressed in microfibrils in ocular zonules	5q32–q33.2
MFAP4	Frequently deleted in Smith–Magenis syndrome	17p11.2
<b>Other Components</b>		
MP78/70 (big-h3)	Mutated in different variants of corneal dystrophy	5q31
Lysyl oxidase	Probably not a structural component	5q23–q31
Lysyl oxidase like 1 (LOXL1)	Cross-linking and scaffold for spatial deposition of elastin	15q24
Emilin (gp115)	At least two isoforms	2p23.3–p23.2

EGF = epidermal growth factor; TGF- $\beta$  = transforming growth factor beta. Data from Uitto, J., Rosenbloom, J. Elastic Fibers. In Freedberg, I. M., Eisen, A. Z., Wolff, K., et al. (Eds); *Dermatology in General Medicine*, 5th edn; McGraw Hill: New York, p. 260.

the functional elasticity of the fibers and manifest as a disease.

### 155.2.2 The Elastin Gene (*ELN*)

The human elastin gene, localized to the long arm of chromosome 7, consists of 34 exons spanning ~45 kb (5) (see Figure 155-3A). These exons correspond to a full-length cDNA of ~3.5 kb, which encodes approximately 800 amino acids in a polypeptide of 70 kDa (6).

A remarkable feature of the human elastin gene is that its pre-mRNA undergoes extensive alternative splicing, a number of exons being post-transcriptionally deleted (6,9). Since these physiological deletions of individual exons are in frame, the alternative splicing results in synthesis of an ensemble of tropoelastin polypeptides with slight variations in their primary sequences. The physiological or developmental significance of the alternative splicing in elastin is unknown, but the observations suggest that small insertions or deletions in the gene, if in frame, are unlikely to result in pathology.

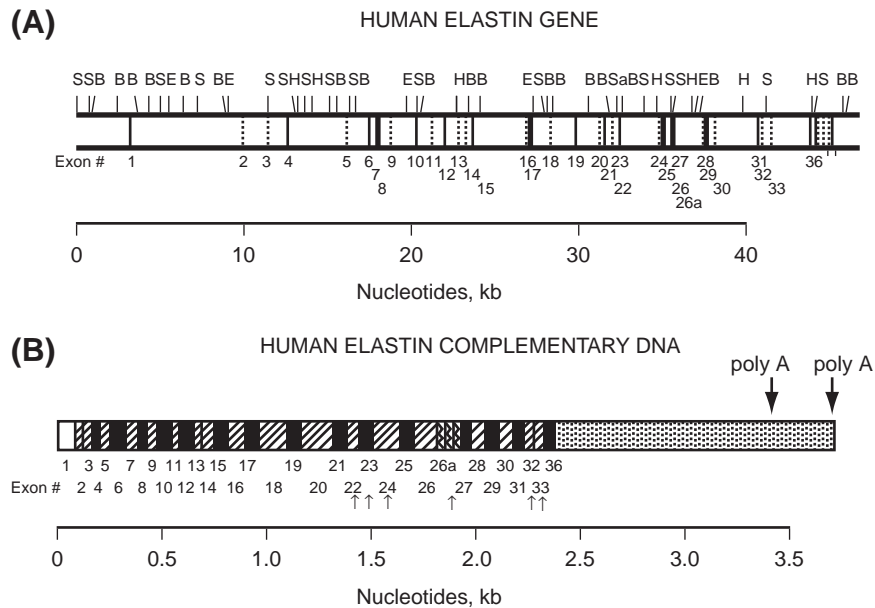

### 155.2.3 Degradation and Remodeling

Although the metabolic turnover of elastin is very slow as compared with proteins in general, a portion of the body's elastin is continuously degraded and may in part be replaced by newly synthesized fibers (10). In addition, degradation of elastin is markedly increased in a variety of pathologic conditions. Thus, the tissues containing elastin must contain proteolytic enzymes that are capable of degrading elastic fibers. Evidence for a specific elastolytic enzyme, elastase, was first obtained from study of the pancreas, and the properties of pancreatic elastase have since been extensively investigated. Subsequently, elastolytic enzymes were detected in several other tissues as well as in a variety of cell types, including polymorphonuclear leukocytes, monocyte/macrophages, and platelets (11).

The classic elastases are serine proteases that degrade insoluble elastic fibers at neutral or slightly alkaline pH. The activity of these enzymes is inhibited by serum factors such as  $\alpha$ 1-antitrypsin and  $\alpha$ 2-macroglobulin. Other elastases have been shown to be metalloenzymes requiring calcium for their activity (12). One such enzyme is secreted by macrophages isolated from peritoneal inflammatory exudates, and this metalloenzyme is different from leukocyte or pancreatic elastases in that it cleaves elastin at peptide bonds at the amino side of leucyl or isoleucyl residues. A similar  $\text{Ca}^{2+}$ -dependent metalloenzyme has been demonstrated in human skin fibroblast cultures (11).

### 155.2.4 Pathology of the Elastic Fibers

The biosynthetic pathways involved in the fibrillogenesis and degradation of the elastic fibers must be carefully controlled to allow maintenance of an optimal level of functional elastic fibers in tissues. If the balance in the rate of biosynthesis or degradation, or both, of the elastic fibers is perturbed, the steady-state level of such fibers could be altered, manifesting as a disease. Furthermore, structural alterations due to genetic mutations in the genes encoding any of the components of the elastic fibers or in the enzymatically mediated post-translational events, such as the cross-linking of elastin, could lead to pathology. In fact, several heritable and acquired

**FIGURE 155-3** Schematic representation of the human elastin gene (A) and the human elastin complementary DNA (B). (A) The gene (*ELN*) consists of 34 exons numbered starting from the 5' end. (Note that the last exon is numbered 36 to be consistent with the bovine elastin gene structure.) The exons are drawn to scale and span ~45 kb of genomic DNA on the long arm of chromosome 7. (B) The human elastin cDNA, ~3.5 kb, has a 2.4-kb coding region corresponding to the 34 exons in the gene. The exons subjected to alternative splicing are indicated by arrows.

**FIGURE 155-4** Formation of covalent intermolecular cross-links, desmosines, between two tropoelastin polypeptides. (A) Amino acid sequences at a potential cross-link region within the elastin polypeptides. Note the presence of paired lysine residues separated by two or three alanine residues and depicting free  $\epsilon$ -amino groups ( $\text{NH}_2$ ). (B) Three of these  $\epsilon$ -amino groups are converted to corresponding aldehydes, allysine residues, by the action of lysyl oxidase, a copper-dependent enzyme. (C) Three of the aldehyde residues and a lysine residue with an unmodified  $\epsilon$ -amino group fuse to form a stable ring-like structure, desmosine, which covalently links the two polypeptides into an insoluble elastic structure. (Modified from Uitto, J.; Rosenbloom, J. *Elastic Fibers. In Dermatology in General Medicine, 5th edn; Freedberg, I. M., Eisen, A. Z., Wolff, K., et al., Eds.; McGraw Hill: New York, 1999; p. 260.*)

connective tissue diseases have been shown to affect the elastic fibers (see Table 155-3). In some of these conditions, mutations can be found in the genes encoding the elastic fiber components, i.e. elastin and the associated microfibrils, and such diseases could be considered as primary heritable elastic fiber disorders. In other heritable conditions, the primary defect may reside in genes other than those encoding the components of the elastic fibers. In such conditions, even though the elastic fibers are clearly abnormal, the pathology is secondary to an unrelated primary event. Finally, in a number of acquired connective tissue disorders, elastic fibers are altered in such a manner that the changes contribute to the clinical presentation, thus producing a phenocopy of their heritable counterparts (13,14).

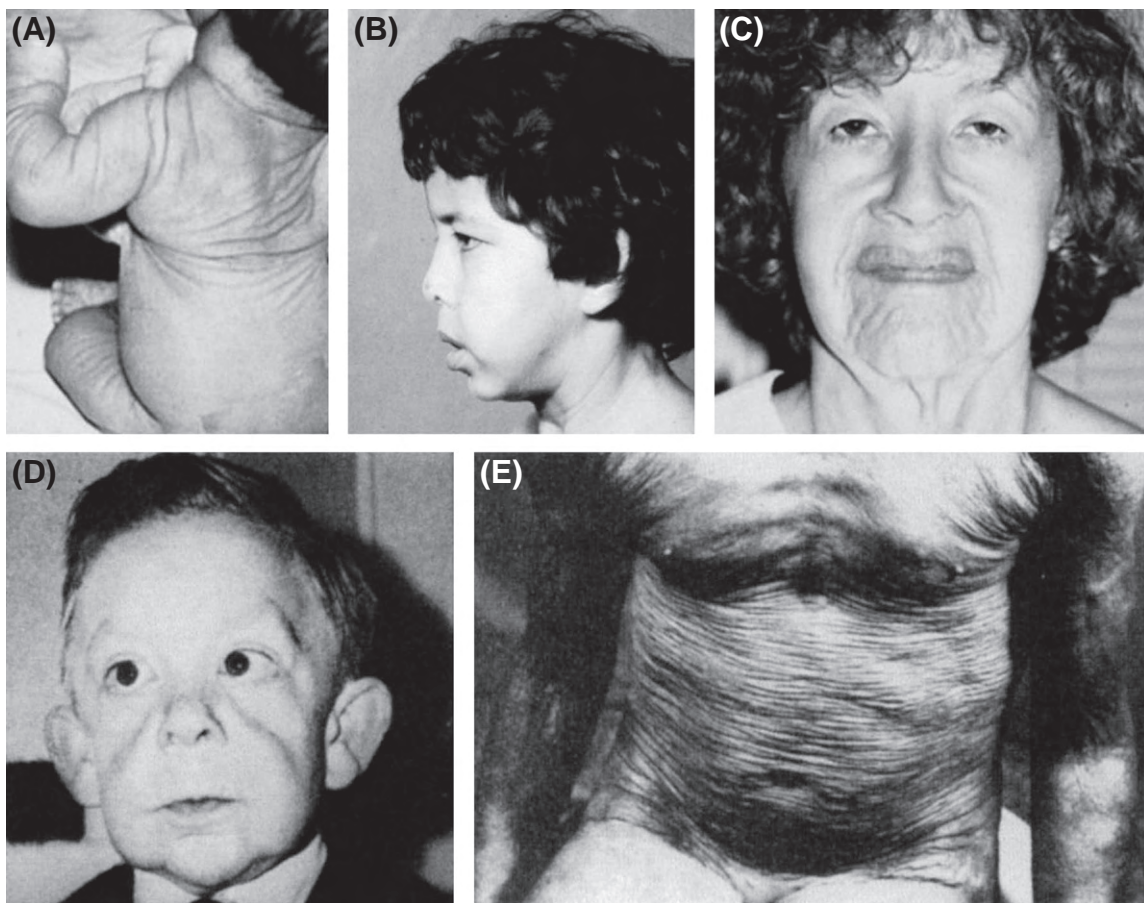

In this overview, the heritable disorders affecting the elastic fibers have been divided into three broad categories, based primarily on clinical findings and histopathological observations of elastic fibers. These three groups include: (1) diseases manifesting primarily with lax skin and associated features due to loss of functional elastic fibers, such as the cutis laxa syndromes; (2) those where elastin accumulation in tissues is a predominant

histopathologic feature, resulting in generalized or localized lesions, as exemplified by cutaneous elastomas and pseudoxanthoma elasticum; and (3) those in which abnormalities in elastin fibrillogenesis can explain the clinical phenotypes as due to lack of functional elastic fibers, as in copper deficiency syndromes.

### 155.3 ELASTIN DEFICIENCY DISORDERS

#### 155.3.1 Cutis Laxa and Other Lax Skin Syndromes

**155.3.1.1 Diagnostic Features and Inheritance.** Cutis laxa (Online Mendelian Inheritance in Man (OMIM) 123700, 219100) is clinically defined as loose and sagging skin that demonstrates reduced elasticity and resilience (Figures 155-5 and 155-6). In some patients the clinical findings are limited to the skin, the phenotype being primarily of cosmetic concern. In other cases, however, the cutaneous findings are associated with a number of extracutaneous manifestations, including pulmonary emphysema (see Figure 155-6D), vascular malformations, umbilical and inguinal hernias, and gastrointestinal and

**FIGURE 155-5** Clinical features of cutis laxa. Note loose and folded skin in an infant (A), sagging jawline in a 4-year-old boy (B), premature aging appearance in a 30-year-old female (C), characteristic facial features in a patient with autosomal recessive cutis laxa (D), and generalized mid-truncal wrinkling as a consequence of an inflammatory urticarial reaction (E). (D is from Pope, F. M. *Pseudoxanthoma Elasticum, Cutis Laxa, and Other Disorders of Elastic Tissue*. In *Principles and Practice of Medical Genetics*, 3rd edn; Rimoin, D. L., Connor, J. M., Pyeritz, R. E., Eds.; Churchill Livingstone, New York, 1997; p. 1083. E is from Verhagen, A. R., Woerdeman, M. J. *Post-inflammatory elastolysis and cutis laxa*. *Br. J. Dermatol.* 1975, 92, 183–190; with permission.)

vesico-urinary tract diverticuli, which cause considerable morbidity and mortality. In fact, in the most severe cases, cutis laxa is lethal during the early postnatal period, primarily from pulmonary complications.

Clinical findings consistent with cutis laxa can also be part of the normal aging process affecting the skin or associated with other heritable connective tissue disorders, particularly some variants of Ehlers–Danlos syndrome (15) (see Chapter 154). In the latter patients, the primary pathology resides in the collagen meshwork, and they should not be diagnosed as having cutis laxa. This diagnosis should be reserved specifically for those conditions in which abnormalities either in the structure or quantity of elastic fibers can be demonstrated by histopathological and ultrastructural means.

The inheritance of cutis laxa is variable, and both autosomal dominant (OMIM 123700) and autosomal recessive (OMIM 219100) patterns occur (16–19). In some cases, typical phenotypic findings are present at birth or will be noted shortly thereafter, while in many cases the onset is delayed even by several decades (20). It should also be noted that many cases with late-onset cutis laxa are, in fact, a distinct acquired variant that results from inflammatory tissue reaction (14,21). Such inflammatory reactions can be due to allergic drug eruption or they initially manifest with urticarial lesions in the skin. Phenotypically, these late-onset acquired forms of the disease can be indistinguishable from milder heritable forms of cutis laxa, in which the findings are limited to the skin.

Histopathology of skin in patients with cutis laxa, using special “elastin-specific” stains (Verhoeff–van

Gieson and orcein), reveals loss, fragmentation, or both, of elastic fibers. In particular, in the newborns with severe cutis laxa, the elastic fibers can be essentially absent. In many cases with late-onset cutis laxa, the elastic fibers are present but fragmented, with absence of contiguous functional elastic fibers (see Figure 155-6C). In these cases, electron microscopy similarly demonstrates irregular fragmentation of the fiber structure. In addition to elastic fiber abnormalities, ultrastructural alterations in collagen fibers have also been described in families with cutis laxa (22). The collagen changes, however, are likely to reflect the overall perturbation of the extracellular matrix of connective tissue, as a result of altered mechanical properties in the skin.

**155.3.1.2 Molecular Mechanisms.** The biochemical and genetic events leading to loss, fragmentation, or both, of the elastic fibers in most cases with cutis laxa are unknown. Consistent with the notion that the elastin gene expression is primarily perturbed in some cases of cutis laxa, it has been demonstrated that elastin mRNA steady-state levels can be reduced in patients with severe congenital forms of the disease (23,24). Specifically, quantitation of elastin mRNA in these patients, either by northern analysis or by slot-blot hybridizations in fibroblast cultures, has revealed that elastin gene expression may be essentially undetectable or clearly less than 10% of the level noted in healthy unrelated controls (Figure 155-7). Although the reasons for reduced steady-state levels of mRNA could be multiple (e.g. reduced rate of transcription or decreased stability of the transcript), the end result would be the same, i.e. less elastin protein being synthesized in the skin and possibly other tissues affected in these patients. Subsequently, there have been reports to suggest the presence of specific mutations in the elastin gene, presumably giving rise to autosomal dominant forms of the disease. One of the first of these patients, a 37-year-old female, was noted as a newborn to have heavy folds under her chin and across her chest, abdomen, groin, and thighs (25). She had multiple facial cosmetic surgeries from 4 years of age on. She also had multiple peripheral pulmonary stenoses; bilateral herniorrhaphies were performed at the age of 7 years, and right ventricle hypertrophy was noted at 19 years of age. Her father had similarly loose skin on his chest, forearms, and abdomen, in addition to facial drooping. Histopathology revealed markedly reduced quantities of dermal elastic fibers, and these fibers appeared fragmented. Sequencing of the elastin gene (*ELN*) revealed deletion of a single adenine in codon 748 within exon 32 (Figure 155-8). This mutation was also present in the proband's father, but not in her mother. Scanning of the second elastin allele did not reveal the presence of any pathogenetic mutations. The mutation causes a frame-shift, which results in replacement of 37 carboxy-terminal amino acids in the elastin polypeptide by a novel 62 amino acid missense sequence. Analysis of mRNA and

**FIGURE 155-6** Clinical, histopathological, and radiological findings in a patient with autosomal recessive cutis laxa. (A) Loose and sagging facial skin in this 15-year-old male. (B) His hands show fine wrinkling giving the premature aging appearance, acrogeria. (C) Histopathology of skin with orcein stain reveals fragmentation of elastic fibers. (D) Chest radiograph reveals findings consistent with severe pulmonary emphysema. Note the infiltrate in the left lung.

Another study similarly identified two frameshift mutations (c.2012delG and c.2039delC) in exon 30 of

the elastin gene (26) (see Figure 155-8). Transcripts from these mutated alleles were unstable, but complicating the interpretation of the data was the suggestion that exon 30 undergoes alternative splicing in fibroblasts. Nevertheless, these mutations were interpreted to be “dominant-acting” and responsible for qualitative and quantitative defects in elastin, resulting in the cutis laxa phenotype. Collectively, these two reports suggest that primary mutations in the elastin gene can be responsible for certain forms of cutis laxa, the mechanism being potentially dominant-negative, and similar observations have been subsequently made in additional cases with an autosomal dominant mode of inheritance (19,27,28).

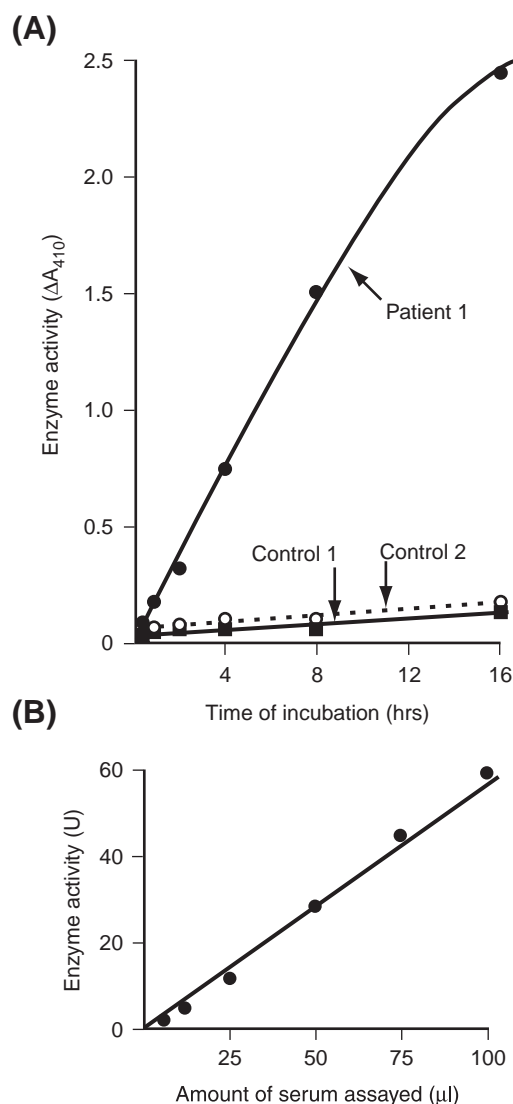

An alternate mechanism for the development of the cutis laxa phenotype is enhanced degradation of the elastic fibers, as illustrated by an intriguing case with cutis laxa and severe pulmonary emphysema (OMIM 235360). This patient also had severe congenital hemolytic anemia of unknown type (29,30). At the age of 15 years, pulmonary emphysema was documented by radiography and pulmonary function tests (see Figure 155-6). Most notably, the vital capacity was 63%, the total lung capacity 183%, and the residual volume 630% of the predicted age-matched values, consistent with severe pulmonary emphysema (29). At the same time, the patient was noted to appear much older than his chronologic age, with sagging skin on the face and neck, as well as premature wrinkling appearance on the backs of his hands (acrogeria) (see Figure 155-6A and B). Histopathologic examination of the skin revealed paucity and fragmentation of the elastic fibers (Figure 155-6C). Laboratory values, specifically  $\alpha$ 1-antitrypsin, as well as serum copper and ceruloplasmin levels, were within the normal range. The patient died at the age of 20 years from the complications of pulmonary emphysema.

The patient had two affected siblings, an older sister and a younger brother, who had died of complications of hemolytic anemia at the ages of 3 and 7 years, respectively. The autopsies revealed emphysematous lung changes in both siblings. A 9-year-old sister and both parents were phenotypically normal, and there was no other family history of similar clinical problems. Thus, the inheritance of cutis laxa, pulmonary emphysema, and hemolytic anemia in this family was consistent with an autosomal recessive pattern.

A possible mechanism leading to cutis laxa and pulmonary emphysema in this individual was provided by observations that the activity of an elastase-like enzyme, measured by degradation of a synthetic substrate, succinyl-(L-alanyl)<sub>3</sub>-p-nitroanilide (SAPNA) (31), was markedly elevated as compared to healthy unrelated controls (Figure 155-9). Specifically, the enzyme activity in this patient's serum was more than 80-fold higher than in the controls. Further characterization of this enzyme indicated that the activity was highest at a neutral or slightly alkaline pH, around 7.6, and that the activity could be inhibited by Na<sub>2</sub>EDTA, suggesting that the enzyme

requires a divalent cation for its activity. The activity was not inhibited by serum protease inhibitors (30). It is conceivable, therefore, that enhanced elastase-like activity was responsible for degradation of elastic fibers both in the skin and the lungs of this patient, resulting in a combined phenotype of cutis laxa and pulmonary emphysema.

In addition to elastin, a limited number of mutations in cutis laxa have been disclosed in the *FBLN5* gene encoding fibulin-5, a microfibrillar component of the elastic fibers. Among them, a recurrent homozygous missense mutation (p.S227P) was reported in two

**FIGURE 155-9** Demonstration of markedly elevated elastase-like enzyme activity, determined by degradation of synthetic small molecular peptide (SAPNA; see text) in serum of the patient with cutis laxa presented in Figure 155-6, as compared to unrelated healthy controls (A). The second graph demonstrates that the enzyme activity assay is linear with respect to the amount of serum assayed (B). (Modified from Anderson, L. L.; Oikarinen, A.; Ryhanen, L., et al. Characterization and Partial Purification of a Neutral Protease from the Serum of a Patient with Autosomal Recessive Pulmonary Emphysema and Cutis Laxa. *J. Lab. Clin. Med.* 1985, 105, 537–546.)

independent families of Turkish and Iranian ancestry, both with severe autosomal recessive cutis laxa (32,33). In another patient with relatively mild cutis laxa with redundant, loose skin and mitral valve regurgitation, a heterozygous *FBLN5* mutation was discovered. The mutation consisted of an internal 483-bp duplication in the fibulin-5 mRNA, resulting in the synthesis and secretion of a mutant fibulin-5 protein with four additional tandem calcium-binding epidermal-growth-factor-like motifs. The mutation arose from a 22-kb tandem gene duplication, encompassing the sequence from intron 4 to exon 9 (34). In addition to fibulin-5, the fibulin-4 gene has been suggested to harbor mutations in patients with autosomal recessive cutis laxa. The first described case had a missense mutation (p.E57K) resulting in cutis laxa associated with multiple bone fractures at birth, vascular abnormalities, developmental emphysema, inguinal and diaphragmatic hernias, joint laxity, and pectus excavatum (35). Detailed examination of additional patients with fibulin-4 deficiency has revealed the presence of aortic aneurysms, arterial tortuosity, and vascular stenosis, potentially reflecting the involvement of altered transforming growth factor beta (TGF- $\beta$ ) signaling (36).

Adding to the molecular heterogeneity of cutis laxa are demonstrations of mutations in the *LTBP4* gene associated with an early lethal phenotype of autosomal recessive cutis laxa and severe gastrointestinal and vesico-urinary malformations in four patients (37). This gene encodes latent TGF- $\beta$  binding protein 4, and its absence in the extracellular matrix causes increased TGF- $\beta$  activity, leading to defective elastic fiber assembly in affected tissues. In some patients with autosomal recessive cutis laxa, but without catastrophic pulmonary emphysema, mutations in the *ATP6V0A2* gene have been reported (38). The corresponding protein, the A2 subunit of a vacuolar H<sup>+</sup>-ATPase, located in cell and organelle membranes, is responsible for glycosylation of proteins important for their proper function. It has been suggested that mutations in this proton pump prevent N- and O-glycosylation of extracellular matrix proteins and impaired secretion of tropoelastin, resulting in cutis laxa phenotype (39,40). The clinical phenotype ranges from generalized wrinkled skin to presentation of characteristic cutis laxa, with pre- and postnatal growth delay and skeletal abnormalities.

Mutations in the *PYCR1* gene have also been detected in families with autosomal recessive cutis laxa and progeroid features, as well as in one individual who was believed to have de Bary syndrome (41–43). The corresponding protein, pyrroline-5-carboxylate reductase 1, a mitochondrial enzyme, is critical for proline biosynthesis. Its deficiency causes abnormal mitochondrial morphology in fibroblasts of the affected individuals. Proline is involved particularly in the biosynthesis of extracellular matrix proteins, as well as in the oxidative cell cycle, and it is plausible that these activities contribute to the progeroid changes in the affected individuals.

Finally, the cutis laxa phenotype has been encountered in patients with MACS syndrome (macrocephaly, alopecia, cutis laxa, and scoliosis). This syndrome is caused by mutations in the *RIN2* gene, encoding a ubiquitously expressed Ras- and Rab-interactor protein involved in the regulation of endocytic trafficking (44,45). *RIN2* deficiency was found to be associated with paucity of dermal microfibrils and deficiency of fibulin-5, which may underlie the cutaneous phenotype in these patients. Collectively, these findings attest to considerable molecular heterogeneity of cutis laxa.

### 155.3.2 Acquired Cutis Laxa

The proteolytic mechanisms in the patient with increased elastase-like enzyme activity may be analogous to some cases with acquired forms of cutis laxa, demonstrating extensive sagging of the skin with little or no evidence of internal organ involvement. However, the skin involvement can be generalized or localized (14). Frequently, these individuals experience an inflammatory reaction in their skin, sometimes associated with allergic drug eruption, which within ensuing weeks or months can result in rapidly progressing premature aging and sagging of the skin, resulting in a phenocopy of the heritable forms of cutis laxa. The acquired cutis laxa phenotype can be associated with a number of conditions, including multiple myeloma, Sweet's syndrome, and urticarial vasculitis. In the cases with inflammatory cutaneous reaction, a possible explanation is that the inflammatory cells, such as polymorphonuclear leukocytes or monocyte-macrophages, release powerful elastases that become activated and result in proteolytic degradation of the elastic fibers. As a consequence, the elastic fibers become progressively degraded and reduced in number, with phenotypic consequences of sagging skin.

The inflammatory destruction of elastic fibers in acquired cutis laxa has been suggested, in some cases, to be associated with missense alleles in the elastin and fibulin-5 genes (46). Specifically, a patient who developed acquired cutis laxa following *Toxocara canis* parasite infection was heterozygous for a fibulin-5 mutation (p.G202R) and compound heterozygous for elastin alleles p.A55V and p.G773D. Western analysis revealed abnormal proteolytic processing of tropoelastin in the patient's fibroblasts, suggesting that the observed sequence variants render the elastic fibers susceptible to inflammatory destruction mediated by proteases.

### 155.3.3 Anetoderma

A pathomechanistically similar, yet phenotypically distinct, situation may involve anetoderma, usually an acquired condition with clinical, histopathological, and electron microscopic features of cutis laxa within the isolated cutaneous lesions in the skin in a limited distribution. Familial occurrence of anetoderma has also been

reported in a few cases, and both dominant and recessive inheritance patterns have been suggested (47–49). Individuals with anetoderma develop numerous protruding sac-like cutaneous lesions (Figure 155-10). Histopathology and electron microscopy of the lesional skin demonstrate that the elastic fibers are irregularly fragmented (see Figure 155-10). The concentration of elastin, determined by radioimmunoassay of desmosine, an elastin-specific cross-link compound, is markedly reduced in the lesional skin, as compared with unaffected skin from the same patients, as well as with normal skin from unrelated control subjects (50). Histopathology and immunohistochemical studies showed that the lesional areas of skin often contain inflammatory cell infiltrates in association with immune complexes and complement (51). It

is conceivable, therefore, that these inflammatory cells release proteases responsible for degradation of elastic fibers in the lesional areas of skin. Traditionally, anetoderma has been divided into inflammatory (Jadassohn) and noninflammatory (Schweninger-Buzzi) types. This distinction is not very clear, however, and it appears that anetoderma represents a continuum of the degree of inflammation, with the unifying pathomechanism of proteolytic degradation of the elastic fibers.

### 155.3.4 Wrinkly Skin Syndrome

A number of conditions with cutaneous features of cutis laxa have been reported as distinct clinical entities. One of them is wrinkly skin syndrome (OMIM 278250), a rare autosomal recessive disorder primarily reported in Middle Eastern ethnic groups. Cutaneous features in these patients are reminiscent of those in cutis laxa. Specifically, skin over the abdomen and dorsum of the hands and feet appears wrinkled, the elasticity of the skin in the affected areas is reduced, and there is an increase in palmar and plantar creases (52,53). In fact, it has been suggested that wrinkly skin syndrome and cutis laxa represent the same disorder (54). However, unlike in cutis laxa, mental retardation, microcephaly, hypotonia, and musculoskeletal connective tissue abnormalities seem to be regular features of this syndrome. Nevertheless, similar to cutis laxa, the elastic fibers in the mid-reticular dermis are fragmented and distorted in structure (52).

The molecular basis of wrinkly skin syndrome is currently unknown, although it has been observed that manifestations of this syndrome are associated in some patients with deletions in the q32 region of chromosome 2 (55). It should be noted that two collagen genes, *COL3A1* and *COL5A2*, reside in this region of chromosome 2, perhaps making them candidate genes for this condition.

### 155.3.5 Mid-Dermal Elastolysis

This condition was initially reported as an acquired non-inflammatory disease in young adults with a pathognomonic histopathologic finding: band-like loss of elastic fibers in the mid-dermis (56). Clinically, these individuals manifest with fine wrinkling, usually affecting large areas of skin on the upper arms and the upper back, primarily in young women (57,58). There is usually no family history, and the cardinal clinical finding (i.e. very fine wrinkling of the skin) is often accentuated on the sun-exposed areas. In analogy to anetoderma, a suggestion has been made to divide this condition into inflammatory and noninflammatory variants (59). However, since preceding inflammation may have already subsided, and only the sequelae of the inflammatory reaction are evident at later stages, this distinction may not have any etiologic or pathomechanistic significance. Finally, these individuals, as a rule, do not demonstrate internal organ

**FIGURE 155-10** Clinical, histopathologic, and electron microscopic observations in a patient with anetoderma. (A) The patient demonstrates numerous protruding sac-like lesions on the upper back. (B) Histopathology reveals loss and fragmentation of elastic fibers in the papillary dermis (Verhoeff–van Gieson stain). Transmission electron microscopy shows markedly fragmented elastic fibers in the papillary dermis (C) and the deep reticular dermis (D) of the lesional skin. (Modified from Oikarinen, A. I.; Palatsi, R.; Adomian, G. E., et al. Anetoderma: Biochemical and Ultrastructural Demonstration of an Elastin Defect in the Skin of Three Patients. *J. Am. Acad. Dermatol.* 1984, 11, 64–72.)

involvement. Thus, mid-dermal elastolysis appears to be an acquired skin condition limited to the mid-dermis, displaying features of an autoimmune process (60). This condition should be recognized in differential diagnosis of heritable forms of cutis laxa.

### 155.3.6 De Barsy Syndrome

Another condition characterized by defective development of elastic fibers in the skin with accompanying cutis-laxa-like features is de Barsy syndrome (OMIM 219150), an autosomal recessive disorder characterized by progeria-like appearance with distinct facial features (61,62). In addition to skin findings, this complex disorder is characterized by severe developmental problems affecting a number of organs, such as the eyes (corneal opacities). The syndrome includes dwarfism and extensive neurological abnormalities, including hypotonia, mental retardation, and congenital bilateral athetosis. Elastic fibers in the skin have been shown to be frayed and reduced in number and density, and examination of the elastin mRNA levels by northern hybridizations has suggested reduced gene expression (63). Thus, these patients have associated features of cutis laxa, but the underlying molecular defects in this multisystem disorder are currently unknown. However, as noted above, a patient with cutis laxa due to mutations in the *PYCR1* gene has been suggested to have de Barsy syndrome (43).

### 155.3.7 Michelin Tire Baby Syndrome

This is another rare condition with fragmentation and paucity of elastic fibers (OMIM 156610). Specifically, these patients demonstrate large skin folds, and histopathology has revealed fragmented elastic fibers, with the amount of elastin being decreased (64) (Figure 155-11). However, the primary pathology in these cases appears to be unrelated to elastin, and the peculiar appearance in most cases is due to an underlying nevus lipomatosus and/or generalized smooth muscle hamartomas (65–67). A child with features of Michelin tire baby with smooth muscle hamartomas, and in addition, multiple anomalies, had a familial paracentric inversion of chromosome 7q (68). It has been suggested that this disease is inherited as an autosomal dominant trait (69,70).

## 155.4 ELASTIN ACCUMULATION DISEASES

### 155.4.1 Pseudoxanthoma Elasticum

#### 155.4.1.1 Diagnostic Features and Inheritance.

Pseudoxanthoma elasticum (PXE; OMIM 264500) has been traditionally considered as a systemic connective tissue disorder affecting the extracellular matrix in various organs of the body (71,72). PXE was initially delineated as a clinical entity distinct from xanthomas (hence pseudoxanthoma) over a century ago (73). During

**FIGURE 155-11** Clinical and morphologic presentations of Michelin tire baby syndrome. (A) A 15-month-old patient demonstrates prominent folds on the leg. (B) Histopathology reveals fragmented elastic fibers surrounding smooth muscle bundles (Weigert's stain). (C) Transmission electron microscopy reveals fragmentation of elastic fibers and paucity of elastin (star), while collagen fibers appear normal (asterisk). (Modified from Sato, M.; Ishikawa, O.; Miyachi, Y., et al. *Michelin Tire Syndrome: a Congenital Disorder of Elastic Fiber Formation?* Br. J. Dermatol. 1997, 136, 583–586; reproduced with permission.)

the ensuing decades, various clinical observations, histopathology, and ultrastructural findings suggested that the primary pathology resides in elastic fibers. Consequently, PXE was considered as a prototype of heritable connective tissue disorders with primary involvement of the elastic fiber system. Recent studies have clearly shown that the classic PXE is caused by mutations in the *ABCC6* gene, a putative transmembrane efflux transporter expressed primarily in the liver and the kidneys (74). Based on these and related observations, PXE is now considered to be a metabolic disorder (see below).

The clinical manifestations of PXE center on three major organ systems of the body, the skin, the eyes, and the cardiovascular system. The presenting manifestations are usually evident in the skin as small yellowish papules, which tend to coalesce into larger plaques, and eventually involve the entire skin (Figure 155-12). The affected skin becomes progressively lax, redundant, and inelastic, causing an appearance of premature aging and eventually having considerable cosmetic impact. Histopathologic evaluation of skin reveals accumulation of pleomorphic elastotic material, as revealed by “elastin-specific” stains (such as Verhoeff–van Gieson and orcein) (Figure 155-13) (75). More remarkably, these pleomorphic elastotic structures become calcified in a progressive manner over the lifetime of the affected individual (see Figure 155-13). Thus, skin biopsy demonstrating

mineralization of aberrant elastic fibers in the mid-dermis is essential in confirming the diagnosis of PXE. This diagnosis can be further supported by demonstration of mutations in the *ABCC6* gene.

The eyes are involved, with characteristic appearance of angioid streaks, which result from fractures in Bruch’s membrane, an elastin-rich sheath within the retina (see Figure 155-12D). As a result of fragmentation of this membrane, there is breakage of retinal blood vessels and neovascularization sets in from the adjacent choroid plexus, associated with bleeding in the retina. Consequently, the affected individuals experience progressive loss of visual acuity, which can eventually lead to legal blindness, although entire loss of vision is rare (72).

The vascular involvement may manifest as elevated blood pressure, intermittent claudication, weakened peripheral pulses, and infrequently, internal bleeding primarily from gastric arterial blood vessels (76). In some families, the cardiovascular manifestations predominate and can lead, although rarely, to early myocardial infarcts of the affected individuals in their 1930s or 1940s. There is considerable phenotypic variability, both intrafamilial and interfamilial, and the involvement of any given organ system may predominate in certain families. This variability has presented a diagnostic challenge to accurately identify individuals with PXE on the basis of clinical manifestations (77). Furthermore,

**FIGURE 155-12** Characteristic clinical findings in pseudoxanthoma elasticum. Note small papular lesions on the antecubital fossa (A) and on the site of the neck (B). These primary lesions tend to coalesce into large plaques rendering skin redundant and inelastic (C). Ophthalmologic examination reveals the presence of angioid streaks (D). (Modified from Uitto, J.; Pulkkinen, L.; Ringpfeil, F. *Molecular Genetics of Pseudoxanthoma Elasticum—A Metabolic Disorder at the Environment/Genome Interface?* Trends Mol. Med. 2000, 7, 13–17.)

the clinical manifestations are rarely present at birth and often become evident not until the second or third decade of life, thus complicating and prolonging the process leading to correct diagnosis.

Adding to the complexity and the diagnostic challenge of PXE were early suggestions that both autosomal dominant and autosomal recessive forms of the disease exist. Recent advances in molecular genetics of PXE have, however, clearly established that PXE is exclusively an autosomal recessive disorder (78,79).

**155.4.1.2 Molecular Pathology.** Since the primary pathology of PXE resides in the elastic fibers, the genes involved in the synthesis and assembly of the elastic fiber network in the body were initially considered as the prime candidate genes (80). These include elastin on chromosome 7q, elastin-associated microfibrils, such as fibrillin 1 and fibrillin 2 on chromosomes 15 and 5, and lysyl oxidase, a copper-dependent enzyme necessary for cross-linking of the elastic fibers, on chromosome 15. In addition, members of the microfibrillar protein family on chromosomes 1, 2, 5, and 15 were considered as potential candidate genes (see later discussion). However, early genetic linkage analyses excluded these chromosomal regions (80). Subsequent studies, utilizing positional cloning approaches, provided strong evidence for linkage of the inherited forms of PXE to the short arm of chromosome 16 (81,82), and the critical candidate region was eventually narrowed by the use of informative recombinants to consist of ~500 kb (83,84). Examination of the existing genome database revealed that this region contained four genes, none of which had an obvious connection to the extracellular matrix of connective tissue in general or to the elastic fibers in particular. Systematic sequencing of these candidate genes resulted in identification of mutations in *ABCC6* (OMIM 603234), which encodes ABCC6 (also known as MRP6) protein, belonging to a family of genes encoding multidrug-resistance-associated proteins (85). A large number of pathogenic mutations have since been reported in

this gene (Figure 155-14) (74,86–88). These mutations can now be utilized for confirmation of the diagnosis, for prenatal diagnosis, and for presymptomatic testing in individuals at risk for inheritance of the disease. The latter consideration is particularly important considering the late onset of the manifestations (89). Genetic linkage analyses in various multiplex families have failed to suggest locus heterogeneity in classic forms of the disease, and thus far *ABCC6* seems to be the only gene underlying the PXE phenotype.

The *ABCC6* gene consists of 31 exons dispersed within ~73 kb of DNA on chromosome 16p13.1, and the corresponding mRNA, 4.5 kb, encodes a polypeptide of 1503 amino acids (90,91). The ABCC6 protein is predicted to consist of three transmembrane-spanning domains, composed of five, six, and six transmembrane segments, respectively (see Figure 155-14). The majority of the mutations disclosed thus far reside in the carboxy-terminal half of the protein, affecting primarily the intracellular domains, the nucleotide-binding folds (NBF1 and NBF2) necessary for the function of this protein as a putative transmembrane transporter (see Figure 155-14). Many of the genetic lesions are nonsense mutations or small insertions or deletions resulting in premature termination of translation, or mutations affecting the consensus splice sites and predicted to result in out-of-frame deletion of the mRNAs (92). The premature termination codons, besides predicting synthesis of a truncated polypeptide, may also result in downregulation of the corresponding transcript through nonsense-mediated mRNA decay. In addition, a number of missense mutations, particularly those replacing critical arginine residues within the cytoplasmic domains of ABCC6, have been disclosed. Finally, large recurrent deletions involving the *ABCC6* locus have been found in some families, reflecting genomic instability surrounding the *ABCC6* locus on chromosome 16p.13.1 (93–95). Collectively, these mutations predict markedly reduced or absent activity of ABCC6.

**FIGURE 155-13** Pathology of cutaneous elastic fibers in pseudoxanthoma elasticum. (A) Histopathology with orcein stain of a skin biopsy reveals accumulation of elastotic material in mid-dermis. (B) Staining of an adjacent section demonstrates that these elastotic structures are calcified (von Kossa stain). (C) Transmission electron microscopy reveals depositions of calcium within the elastic fibers (arrow). (Modified from Uitto, J.; Pulkkinen, L.; Ringpfeil, F. *Molecular Genetics of Pseudoxanthoma Elasticum—A Metabolic Disorder at the Environment/Genome Interface?* Trends Mol. Med. 2000, 7, 13–17.)

Particularly intriguing observations with potential pathomechanistic implications for PXE have been made in patients with PXE-like cutaneous findings in

association with vitamin-K-dependent multiple coagulation factor deficiency (96,99,100). These patients show primarily cutaneous lesions similar to those seen in PXE, i.e. small yellowish papules and excessive folding and sagging of the skin and loss of recoil. These patients have been described as having combined clinical features of both PXE and cutis laxa (99). However, cutaneous lesions in these patients depict characteristic mineralization of the elastic structures in the dermis similar to PXE, a finding that is not present in patients with cutis laxa.

The patients with PXE-like cutaneous findings and vitamin-K-dependant coagulation factor deficiency have mutations in the *GGCX* gene encoding  $\gamma$ -glutamyl carboxylase, an enzyme responsible for  $\gamma$ -glutamyl carboxylation of Gla-proteins, including vitamin-K-dependent coagulation factors and matrix Gla-protein (MGP) (101). Most of these patients show inactivating missense mutations in both alleles of *GGCX*, and the absent enzyme activity does not allow activation of the vitamin-K-dependent coagulation factors through  $\gamma$ -carboxylation, thus explaining the bleeding tendency in these patients. The explanation for ectopic connective tissue mineralization in these patients may involve the role of MGP. This protein, in its fully carboxylated form, is a powerful anti-mineralization factor that has the capacity to prevent ectopic mineralization under normal homeostatic levels of calcium and phosphate, as shown by the development of the corresponding knockout mouse, *MGP*<sup>-/-</sup>, characterized by extensive mineralization of connective tissues (102). However, the under-carboxylated form of MGP is inactive, potentially allowing the mineralization process to ensue. Examination of skin lesions in patients with PXE with specific antibodies that distinguish the fully carboxylated and under-carboxylated forms of MGP has suggested that this protein is under-carboxylated in the lesional skin (103,104). A potential explanation for under-carboxylation of MGP in classic PXE involves the possibility that the *ABCC6* protein participates in transmembrane transport and distribution of vitamin K, specifically its reduced form (KH<sub>2</sub>), an obligatory cofactor of  $\gamma$ -glutamyl carboxylase (74,105). In this context, it should be noted, however, that feeding *Abcc6*<sup>-/-</sup> mice with vitamin K does not counteract the mineralization process (106).

Entering to the differential diagnosis of PXE are patients with vascular calcification due to mutations in the *NTSE* gene. These patients present with progressive calcification of arterial blood vessels particularly in lower extremities, associated with calcium phosphate deposits in joint capsules in the hands and feet (107). The histopathology of the calcified arteries is somewhat similar to those in patients with PXE; *NTSE* encodes CD73, a 5' exonucleotidase critical for synthesis of adenosine. It was, therefore, postulated that adenosine has a role in inhibiting aberrant vascular calcification under physiologic conditions. Thus, considering the similarity between PXE and the CD73 deficiency, it was suggested

that adenosine may be one of the molecules physiologically transported by *ABCC6* (108).

A remarkable observation is that *ABCC6* is expressed primarily, if not exclusively, in the liver and the kidneys (90), organs not known to be clinically affected in PXE. This observation raises the question of the relationship between the *ABCC6* mutations and the manifestations in PXE affecting the elastic fibers in various organs. Thus, PXE could be considered as a metabolic disorder rather than a primary connective tissue disease (109,110) (Figure 155-15). In support of the “metabolic hypothesis” are observations that serum from patients with PXE is deficient in anti-mineralization capacity, an observation that has been confirmed with *Abcc6*<sup>-/-</sup> mice. Since *ABCC6* protein in the liver is considered to be an efflux transporter, it is conceivable that in the absence of transport activity, factors contributing to the anti-mineralization capacity of proteins, such as MGP, would be deficient in circulation, allowing the ectopic mineralization to ensue. This mechanism would also explain the delayed onset of the clinical manifestations and the progressive nature of the calcification process. At the same time, it should be noted that while most elastic structures demonstrate histopathological and ultrastructural evidence of mineralization, not all organs rich in elastin are clinically affected in PXE. Specifically, the lungs, tissues rich in elastin, are not affected in PXE (72).

It has been suggested that low level of expression of *ABCC6* can be detected by RT-PCR in cells derived from mesenchymal tissues, such as dermal fibroblasts or vascular smooth muscle cells (86,111). If confirmed, an alternate possibility would be that the absent expression of *ABCC6* modifies the biosynthetic capacity of “PXE cells” in a manner that would result in synthesis of aberrant elastic structures with affinity for calcium. Nevertheless, the critical role of mutations in *ABCC6* resulting in the PXE phenotype has been confirmed by the recent development of a mouse models in which *ABCC6* has been deleted by targeted inactivation (112,113). These mice develop extensive tissue calcification, including skin, retina, and arterial blood vessels, thus recapitulating the histopathologic and ultrastructural features of PXE.

**155.4.1.3 Molecular Diagnostics.** The observations on the mutations in the *ABCC6* gene have raised several intriguing questions regarding the genetics of PXE. One of the issues relates to the mode of inheritance. Traditionally, PXE has been reported to be inherited either in an autosomal recessive or autosomal dominant pattern, and a number of sporadic cases with uncertain inheritance have also been noted. However, there is no molecular evidence of autosomal dominant inheritance in any of the families examined thus far. In some cases, a pseudodominant pedigree structure can explain the inheritance of the disease in two generations, with a mistaken clinical impression of autosomal dominant inheritance (114). Another explanation for the purported autosomal dominant inheritance may reside in the fact that many of the

**FIGURE 155-15** Illustration of the proposed “metabolic hypothesis” of pseudoxanthoma elasticum (PXE). Under physiologic conditions, the ABCC6 protein is expressed in high levels in the liver and serves as an efflux pump on the baso-lateral surface of hepatocytes, transporting critical metabolites from the intracellular milieu to the circulation (right side of the panel). In the absence of ABCC6 transporter activity in PXE, reduced concentrations of such substrate molecules, which may serve as physiologic anti-mineralization factors, are found in the circulation, resulting in mineralization of connective tissues in a number of organs, such as the eye, the arterial blood vessels, the kidneys, and the skin (middle panel). The presence of mineralization is illustrated by histopathologic examination (Alizarin red stain) of tissues in *Abcc6*<sup>−/−</sup> mice that recapitulate the features of human PXE. (Adapted from Uitto, J.; Li, Q.; Jiang, Q. *Pseudoxanthoma Elasticum: Molecular Genetics and Putative Pathomechanisms*. *J. Invest. Dermatol.* **2010**, 130 (3), 661–670; with permission.)

clinical findings in PXE are rather common in the general population, particularly at an older age. Specifically, cutaneous findings mimicking PXE are frequently encountered in older individuals in sun-exposed areas of skin, with characteristic accumulation of elastic material in the mid-dermis (13,115) (Figure 155-16). Furthermore, other diagnostic manifestations of PXE, such as the cardiovascular involvement, are prevalent in the elderly (76). Thus, such individuals may have been thought to be affected with PXE, particularly in families with history of PXE, conveying the impression of autosomal dominant inheritance. At the same time, it has been suggested that heterozygous carriers of PXE mutations may manifest with features of PXE (116–118). However, molecular screening of many such families has revealed *ABCC6* mutations on both alleles of these presumed heterozygous carriers (79).

Although molecular analysis has not yet been supportive, it is conceivable that partial deficiency of ABCC6 function could lead to haploinsufficiency, which, particularly under certain environmental or dietary conditions, would manifest as a milder form of the disease. In this context, it should be noted that the function of the ABC transporter proteins and/or their substrate specificity and flux could be altered by a number of dietary, hormonal, or environmental factors. For example, high intake of dairy products rich in calcium and phosphate during childhood and adolescence has been statistically associated with the severity of PXE (72,119). The role of diet has been experimentally addressed using the *Abcc6*<sup>−/−</sup> mice as a model system. These studies have shown that the mineral content of their diet can clearly modulate the ectopic mineralization process (120–122). However, calcium did not modulate

**FIGURE 155-16** Clinical features and histopathology of skin in sun-damaged area on the neck. Note that the clinical appearance has some resemblance to pseudoxanthoma elasticum (PXE). (A) Histopathology of the skin on the neck reveals massive accumulation of elastotic material (C), as compared to skin in the sun-protected area (buttocks) from the same individual (B). Note that these elastic structures are not calcified, as in PXE (see Figure 155-13).

the degree of mineralization; instead, magnesium, when added to the mouse diet in amounts that increased the magnesium concentration by five-fold over the standard diet, was able to prevent the ectopic mineralization noted in these mice (121). Conversely, an experimental diet with low magnesium was shown to accelerate the mineralization process in *Abcc6*<sup>-/-</sup> mice, as compared with the corresponding mice kept on a standard diet (123). These findings support the notion that changes in the diet can alter the age of onset and extent of mineralization in PXE, and they suggest that dietary magnesium might be helpful for treatment of patients with PXE (124). Similarly, hormonal influence on manifestations of PXE can be inferred from the predominance of female patients with PXE, as well as from reported deterioration of the disease as a result of multiple pregnancies (72). Finally, certain lifestyle variables, such as cigarette smoking, can clearly modify manifestations of PXE, as exemplified by worsening of intermittent claudication.

#### 155.4.2 Elastoderma

This is an extremely rare condition with striking clinical similarity to PXE. Specifically, Kornberg et al. (125) described a 33-year-old female who had an approximately 4-year history of progressive laxity of the skin, primarily on the elbows and knees. Physical examination revealed loose and sagging skin, which upon stretching displayed incomplete and delayed recoil (Figure 155-17A and B). The patient was otherwise in good health, and there was no evidence of internal involvement or eye problems. Examination of a skin biopsy specimen

revealed accumulation of pleomorphic elastotic material in the mid-dermis, as well as surrounding deeper blood vessels on the lower parts of the dermis (Figure 155-17C and D). Both scanning and transmission electron microscopy revealed abnormal elastic structures in association with, if not in direct extension of, normal-appearing elastic fibers (Figure 155-17E and F). The excessive, abnormal-appearing material was more electron dense than the normal elastic fibers.

As a quantitative biochemical measure of the cross-linked elastic fibers, desmosine concentration was also measured in the affected and unaffected skin by radioimmunoassay. The mean concentration of desmosine in the lesional skin was  $260.2 \pm 4.9$  ng/mg wet weight of skin; the corresponding value in the unaffected skin of the same patient was  $70.2 \pm 1.3$  ng/mg, while the desmosine concentration in the skin of nine healthy age-matched controls was  $79.3 \pm 22.7$  ng/mg (125).

The accumulation of abnormal elastic material, as demonstrated by histopathological staining and by desmosine assay, together with the clinical features, is reminiscent of PXE. Remarkably, however, the elastic fibers were not calcified, thus excluding definitive diagnosis of PXE. Furthermore, there was no evidence of generalized elastin problems affecting the internal organs or ophthalmologic findings characteristic of PXE.

Similar clinical, histopathological, and ultrastructural findings were subsequently reported in a 27-year-old male (126). Thus, elastoderma appears to be a rare, yet distinct, entity with accumulation of pleomorphic elastin in the skin. The molecular and genetic bases of this condition remain unknown.

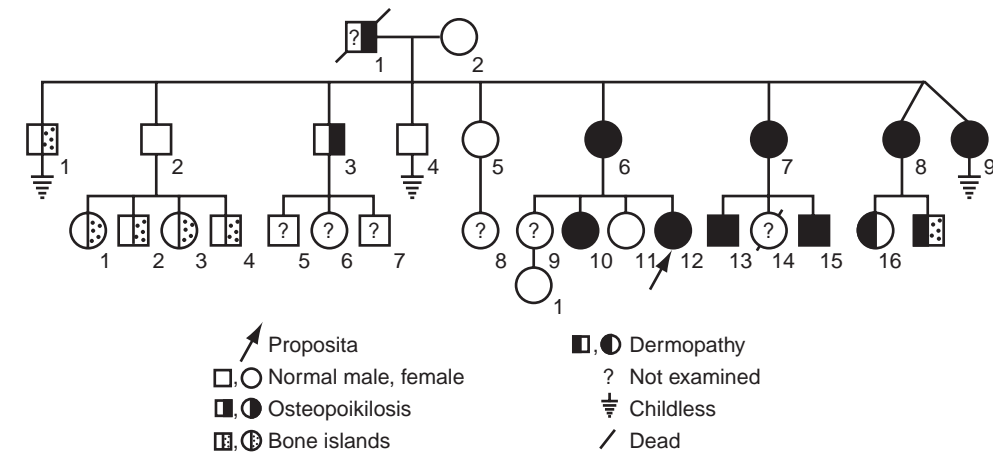

**FIGURE 155-17** Clinical, histopathologic, and ultrastructural features in elastoderma. Note that the patient's skin on the elbow is hyperextendable (A); however, stretching of the skin results in incomplete and delayed recoil (B). Histopathology with elastic stains (Verhoeff–van Gieson) reveals accumulation of pleomorphic elastic structures in the mid-dermis (C) and surrounding a small blood vessel in the deeper dermis (D). The presence of normal-appearing elastic fibers is indicated by arrows in (C). Scanning electron microscopy (E) and transmission electron microscopy (F) demonstrate morphologically altered, electron-dense structures (asterisks) in association with normal-appearing elastic fibers (stars). (A–C, E, F modified from Kornberg, R. L.; Hendler, S. S.; Oikarinen, A., et al. *Elastoderma—Disease of Elastin Accumulation Within the Skin*. N. Engl. J. Med. 1985, 312, 771–774.)

### 155.4.3 Buschke–Ollendorff Syndrome

Buschke–Ollendorff syndrome (OMIM 166700) is characterized by cutaneous findings, known as dermatofibrosis lenticularis disseminata, together with radiologically detectable bone lesions, osteopoikilosis (Figure 155-18A and B) (127,128). This condition is inherited in an autosomal dominant pattern (see top of Figure 155-18), although a few sporadic cases with the syndrome have also been reported. The cutaneous lesions appear as small papules or discs, most commonly found on the lower trunk and extremities. The onset of the skin lesions is usually before puberty, but rarely they may be present at

birth. Pathologic examination of the skin lesions reveals accumulation of elastic structures that are, however, unusually broad and interlacing (see Figure 155-18C). No fragmentation of the fibers is noted. Electron microscopy reveals that these elastic structures are peculiarly branching, and the diameter of individual fibers is highly variable. The accumulation of elastic fibers in the skin has been shown to be associated with elevated production of elastin by cultured dermal fibroblasts (129). Collagen is, for the most part, normal, and the cutaneous lesions appear to be primarily due to accumulation of elastotic material. The accumulation of elastin has also

**FIGURE 155-18** Clinical, histopathologic, and ultrastructural findings in Buschke–Ollendorff syndrome. A large pedigree with characteristic cutaneous lesions and bone findings, with inheritance consistent with autosomal dominant pattern, is shown on the top. The cutaneous findings manifest as groups of small yellowish papules typically on the lower back (A), while the bone changes manifest as radiologically detectable densities at the ends of long bones (B). Histopathology of the skin from the lesional area reveals accumulation of interlacing broadened elastic fibers (C), and transmission electron microscopy reveals, next to a fibroblastic cell (F), irregularly shaped elastic fibers (E), which are deficient in the microfibrillar component (D). (Modified from Uitto, J.; Santa Cruz, D. J.; Starcher, B. C., et al. *Biochemical and Ultrastructural Demonstration of Elastin Accumulation in the Skin Lesions of the Buschke–Ollendorff Syndrome*. *J. Invest. Dermatol.* 1981, 76, 284–287.)

been confirmed by assaying the desmosine content, which indicated that the elastin concentration in the lesions is increased three- to seven-fold (130). Thus, the cutaneous lesions are connective tissue nevi of the elastin type (131).

An integral part of Buschke–Ollendorff syndrome is the presence of osteopoikilosis, which can usually be demonstrated at the ends of long bones (see Figure 155-18B) as well as in the hands of the affected individuals. The relationship between the skin findings and the osteopoikilotic bone lesions is not clear, and the biochemical nature of the osseous lesions is unknown. Histopathology of the osteopoikilotic bone lesions has been reported to consist of foci of compact bone (132). Ordinarily, bone does not contain elastin, and accumulation of elastin at the end of long bones is unlikely. It is perhaps more likely then that the skin findings and the bone lesions result from biochemically unrelated, but genetically closely linked aberrations in these tissues. In support of this interpretation are the observations in a large family with autosomal dominant inheritance of Buschke–Ollendorff syndrome (see Figure 155-18, top). In this family, most affected individuals had complete manifestations of the syndrome (i.e. the presence of skin findings and osteopoikilosis). However, careful examination of a male with osteopoikilotic bone changes failed to reveal the presence of any cutaneous lesions (individual no. 3, second generation). At the same time, another individual (no. 16) clearly demonstrated the presence of skin findings but a complete skeletal radiographic survey failed to find evidence of osteopoikilosis. It should be noted that in a number of individuals (nos. 1–4, third generation), no cutaneous findings were present, and the bone findings consisted of “bone islands,” potential precursors of osteopoikilosis. Collectively, the cutaneous lesions in Buschke–Ollendorff syndrome are asymptomatic, and primarily of cosmetic concern. However, correct recognition of the osteopoikilotic bone lesions as benign and distinction of the cutaneous lesions from those in PXE is critical.

The gene underlying Buschke–Ollendorff syndrome has been identified as *LEMD3*, which encodes an inner nuclear membrane protein (133), and the presence of heterozygous loss-of-function mutations in this gene have been confirmed in several families with Buschke–Ollendorff syndrome or osteopoikilosis alone, while studies on some families have failed to detect exonic mutations in this gene (134–136). The *LEMD3* gene antagonizes bone morphogenic protein and activin–TGF- $\beta$ -receptor-activated Smad signaling pathways, but how these interactions result in accumulation of elastic fibers in the Buschke–Ollendorff patients’ skin remains unclear.

#### 155.4.4 Elastomas

A number of cases with connective tissue nevi with elastin accumulation in the skin, in the absence of

osteopoikilosis, have also been described (130). Although some of these appear to be familial, a number of them are isolated cases with no family history. Some lesions are present at birth or develop at the early stages of life (juvenile elastoma) while others develop later in life. Most of these conditions are asymptomatic and only of cosmetic concern; however, considering the differential diagnosis of other infiltrative processes, a skin biopsy should be performed to confirm the diagnosis of connective tissue nevi of the elastin type.

In some patients, connective tissue nevi of both elastin and collagen type can be found, and some of the lesions seem to be of mixed type, with generalized proliferation of these two fibrillar components of the connective tissue. In some cases, the lesions consist, in addition to extracellular matrix components, of lipids and have been described on histological basis as elastofibrolipomas (137).

A well-defined variant of soft-tissue tumors with distinct accumulation of abnormal elastin is elastofibroma dorsi, a benign tumor characteristically located in the subscapular region (138). Histologically, these lesions consist of collagen and elastin admixed with lipids, and contain an infiltrate of fibroblasts and adipocytes (139). The elastic fibers have a peculiar appearance of globules, either singular or in the form of beaded strings, arranged in a linear fashion. The incidence of elastofibroma dorsi is not known, but this condition, as judged from autopsy findings (140), is relatively common in individuals over 50 years of age. Most cases appear to be sporadic and the mode of inheritance is unknown. However, physical trauma to the subscapular area may play a role in the development of these subcutaneous, poorly defined lesions. Of interest is the observation that elastofibroma dorsi is particularly prevalent in an area of Okinawa, Japan, and many of these patients have a family history of similar lesions (141).

A particular variant of the connective tissue nevi of the elastin type is acrokeratoelastoidosis of Costa (OMIM 101850; 20, 36). This condition manifests with multiple papules on the hands and feet, and histopathology demonstrates accumulation of elastic fibers which are frequently fragmented (elastorrhexis), a finding that can also be detected to a certain extent in the adjacent, clinically unaffected area of skin. The cutaneous lesions also demonstrate foci of hyperkeratosis or acanthosis, which have been considered to be secondary (142). Thus, this condition is regarded as a primary elastic tissue disorder, which can be divided into the hereditary and the acquired type (143). In some families, autosomal dominant inheritance has been suggested (144).

### 155.5 DISORDERS OF ELASTIN FIBRILLOGENESIS

As indicated previously in this chapter, the fibrillogenesis of elastic fibers requires a number of carefully controlled steps. One of the early events is the assembly of

the microfibrillar scaffold into which the elastin molecules align so as to provide directed growth of elastic fibers with a regular, uniform diameter. This process is assisted by a number of elastin-associated microfibrils belonging to different protein families that have been characterized by biochemical and molecular means (see Table 155-3) (1,145–147). Subsequent to their assembly into fibrillar organization, the elastin molecules become extensively cross-linked in a complex reaction initiated by lysyl oxidase, a copper-dependent enzyme expressed in fibroblasts and other elastin-producing cells (see Figure 155-4) (148). Thus, perturbations in the microfibrils, as well as alterations in the activity of lysyl oxidase, can result in abnormalities in the elastic structures. In a number of complex disorders, elastin fibrillogenesis is altered, and the elastic fiber abnormalities are part of a broader spectrum of pathology. At the same time, specific genetic mutations have been described in the microfibrillar proteins, fibrillin 1 and fibrillin 2, resulting in clinical phenotypes of Marfan syndrome and congenital contractural arachnodactyly, respectively. (For discussion of these two conditions, see Chapter 153) Furthermore, mutations in the gene encoding  $\beta$ ig-h3, a component of the elastin-associated microfibrils, have been disclosed in variants of corneal dystrophy (149,150).

Menkes syndrome (see Chapter 100), a complex X-linked disorder, is characterized by developmental delays in maturing neural functions, and associated with a number of features, including connective tissue and hair abnormalities (151,152). In a characteristic case, the skin is easily stretchable and loose, reminiscent of the features in cutis laxa. The hair is brittle and has hair shaft abnormalities, mostly pili torti. Electron microscopic examination of the elastic fibers in the skin has revealed paucity of the central amorphous component consisting of elastin, while the microfibrillar material appears to retain normal morphology (153,154). Menkes syndrome is caused by mutations in the gene encoding a copper transport protein (*ATP7A*) resulting in low serum copper and ceruloplasmin levels and affecting a number of copper-dependent enzymes in different tissues (155–157). In cases with essentially complete absence of *ATP7A* function, the copper levels are extremely low and a multitude of clinical findings can be seen in patients affected with the classic form of Menkes syndrome, including abnormal hair, multiple joint dislocations, seizures, hypotonia, and motor delay with mental retardation. The multitude of neurological, connective tissue, and hair abnormalities can be explained by reduced activities of copper-dependent enzymes, including dopamine  $\beta$ -hydroxylase, cytochrome C oxidase, superoxide dismutase, tyrosinase, and lysyl oxidase (158).

The understanding of Menkes syndrome pathology has been advanced by study of animal models of genetic copper deficiency syndromes. Perhaps the closest animal model for Menkes disease is the brindle mouse mutant

(MObr), which has a two-amino-acid deletion in the highly conserved region of the mouse gene homologous to *ATP7A* (159).

A number of distinct conditions allelic with Menkes syndrome, but with differing phenotypes, have been described. Specifically, a condition known as occipital horn syndrome, previously classified as X-linked cutis laxa or Ehlers–Danlos syndrome type IX, is also due to mutations in *ATP7A*. The primary manifestations of occipital horn syndrome relate to skeletal and connective tissue abnormalities, which could conceivably result from reduced lysyl oxidase activity as a result of low serum copper concentration (160,161). Examination of the mutations and their consequences on the level of expression of *ATP7A* has suggested that partial expression of the gene can occur, and the most severe manifestations of Menkes syndrome are avoided by the residual copper transport activity. A number of cases manifesting the spectrum between full-blown Menkes disease and milder connective tissue manifestations of occipital horn syndrome have also been noted (162,163). For example, in specific families with splice-site mutations in *ATP7A*, approximately 20% of the Menkes gene product has been predicted, and the individuals survive but manifest a number of clinical features associated with Menkes syndrome (163). Thus, these allelic conditions seem to form a continuous spectrum of severity depending on the level of expression of *ATP7A*, as a result of different kinds of mutations in this particular gene.

### 155.5.1 Williams Syndrome and Supravalvular Aortic Stenosis

Another complex developmental abnormality involving the elastic structures is Williams syndrome (OMIM 194050). This disease manifests with a number of developmental and central nervous system problems, as well as characteristic cardiovascular findings (164,165). Specifically, the manifestations include mental retardation, characteristic personality traits, specific cognitive profile, dysmorphic facial features (Figure 155-19), and connective tissue abnormalities. Most patients with Williams syndrome have supravalvular aortic stenosis (SVAS; OMIM 185500), hemodynamically significant narrowing of the aorta, although other arterial blood vessels can also be affected (166). It has been demonstrated that Williams syndrome is a contiguous gene deletion syndrome on chromosome 7q, and the multiplicity of the deleted genes may give rise to the spectrum of phenotype. In case of elastin gene (*ELN*) deletions within the critical interval, cardiovascular manifestations in the form of SVAS accompany the syndrome. This notion is supported by the findings that either familial autosomal dominant or isolated cases with SVAS, without signs of other features of Williams syndrome, are due to mutations in *ELN* (see Figure 155-8) (167). These mutations include nonsense and splice-site mutations, as well as 1-bp deletions

**FIGURE 155-19** Typical facial features of a patient with Williams syndrome. (From Pope, F. M. *Pseudoxanthoma Elasticum, Cutis Laxa, and Other Disorders of Elastic Tissue*. In *Principles and Practice of Medical Genetics*, 3rd edn; Rimoin, D. L., Connor, J. M., Pyeritz, R. E. Eds.; Churchill Livingstone: New York, 1997; p. 1083; reproduced with permission.)

or insertions (168–171), as well as larger deletions and translocations (172–175).

### 155.5.2 Costello Syndrome

This is a complex developmental disorder syndrome characterized by mental retardation, loose skin, coarse facies, skeletal deformities, cardiomyopathy, and predisposition to malignancies (OMIM 218040) (176–179). The main cutaneous findings are loose skin on the hands, feet, and neck, but not on the trunk, as well as deep palmar and plantar creases, palmoplantar hyperkeratosis, and pigmented nevi of the palms and soles. The assembly of elastic fibers in this condition has been shown to be abnormal, in spite of adequate synthesis of elastin and normal deposition of the microfibrillar scaffold (180,181). These observations suggest, therefore, that the elastin abnormalities in Costello syndrome may result from improper interaction between the microfibrillar component and elastin. In support of this interpretation, it has been suggested that the 67-kD elastin-binding protein, which has been suggested to chaperone elastin polypeptides through the secretory pathways for extracellular assembly, is functionally deficient. It has also been postulated that Costello syndrome may result from accumulation of chondroitin sulfate, which causes shedding of this elastin-binding protein from cells, thus contributing to the connective tissue abnormalities in this

complex disorder (180). The genetic basis of Costello syndrome has been shown to be germline mutations in the *HRAS* proto-oncogene (182). In most cases, the genetic lesions are missense mutations in codons 12 or 13, and a potential correlation between the mutation (such as p.G12A) and the risk for malignancy has been suggested (183,184). The details as to how the mutations in *HRAS* might result in elastic fiber abnormalities remain unresolved.

### ACKNOWLEDGMENTS

We thank Drs F Michael Pope and M Sato for providing illustrations. Dr Franziska Ringpfeil contributed to the previous edition of this overview. Carol Kelly provided assistance in preparation of this chapter. The original studies by Dr Uitto were supported by the United States Public Health Service, National Institutes of Health (R01 AR28450).

### Biography

**Jouni Uitto**, MD, PhD, has been Professor of Dermatology and Cutaneous Biology, and Biochemistry and Molecular Biology, and Chair of the Department of Dermatology and Cutaneous Biology at Jefferson Medical College, in Philadelphia, Pennsylvania, since 1986. He is also Director of the Jefferson Institute of Molecular Medicine at Thomas Jefferson University. He received his MD and PhD degrees from the University of Helsinki, Finland, and completed his residency training in dermatology at Washington University School of Medicine, St. Louis, Missouri.

Dr Uitto is internationally recognized for his research on connective tissue biology and molecular genetics in relation to cutaneous diseases. Dr Uitto's publications include 602 original articles in peer-reviewed journals, 278 textbook chapters and review articles, and 901 abstracts on presentations in national and international meetings (April 2011). Dr Uitto has been the recipient of numerous national and international awards, including honorary doctorate degrees from the University of Kuopio, University of Oulu, and University of Turku, all in Finland, as well as honorary professorship at China Medical University, Shenyang.

Dr Uitto has held office in several scientific and professional societies, including as President of the Society for Investigative Dermatology and President and Chairman of the Board of Trustees of Dermatology Foundation. Dr Uitto is also Section Editor of the *Journal of Investigative Dermatology*, Associate Editor of the *American Journal of Pathology*, and he is on the editorial boards of numerous peer-reviewed journals.

### GLOSSARY

**Dual-Energy X-ray Absorptiometry (DXA)** – This two-dimensional, quantitative technique uses an X-beam with two distinct energies, which get attenuated differently in bone and soft tissue. By measuring the posterior–anterior X-ray absorption profile, bone density ( $\text{g}/\text{cm}^2$ ) and tissue fat is determined. Bone area ( $\text{cm}^2$ ), bone mineral content, and lean tissue can also be derived. The values are compared with those of normal age-, sex-, and height-matched controls and reported as standard deviation or z-scores. The usual sites measured are the total body, lumbar spine, forearm, and proximal femur.

**Platyspondyly** – A general technical term describing reduction in height (flattening) of vertebrae seen in the sagittal plane.

**Peripheral Quantitative Computerized Tomography (pQCT)** – pQCT uses computer tomography to perform a three-dimensional measurement of bone structure. This enables the separate determination of trabecular and cortical bone density ( $\text{g}/\text{cm}^3$ ), bone mineral content, cross-sectional area, and strength-strain indexes in discrete regions of the peripheral skeleton. Currently, the common sites measured are the 4% and 65% sites of the forearm and tibia.

**Wormian bones** – Small plate-like bones along cranial sutures, particularly lambdoid and parieto-occipital bones identified by the physiologist Olaus Wormius. Found in higher frequency in certain dysplasias of the mineralized skeleton and premature aging disorders.

### 156.1 INTRODUCTION

This large group of genetic disorders of the skeleton consists of diseases characterized by decreased bone density and abnormal biomechanical properties of bone, e.g. bone fragility and impaired longitudinal growth. Notwithstanding this definition, there is considerable variability in all these disorders reflecting different manifestations at different ages, and the impact of different classes of mutations in the same molecules.

Decreased bone density, as measured by dual-energy X-ray absorptiometry (DXA), may result from reduced production, defective mineralization, or increased breakdown of normal or defective bone, or a combination of these. Osteomalacia (i.e. undermineralized bone) characterizes hereditary rickets and other disorders leading to defective mineralization. Osteopenia (insufficient bone) characterizes the hereditary osteoporoses and many other genetic and acquired diseases of childhood. Osteoporosis (i.e. the clinical syndromes resulting from osteopenia) is characterized by liability to fractures, particularly crush fractures of the vertebrae. The osteogenesis imperfecta (OI) syndromes are numerically the most frequent of the heritable syndromes with osteoporosis.

### 156.2 OSTEOGENESIS IMPERFECTA

The term osteogenesis imperfecta was proposed by Vrolik in 1840 to explain the origin of a hereditary skeletal

condition leading to susceptibility to fracture and severe skeletal deformity. Also known as fragilitas ossium, osteopsathyrosis, and Ekman–Lobstein or Vrolik disease, OI is characterized by increased bone fragility and decreased bone mass. There is significant variability in the clinical features and severity within OI. The extreme variability in OI results in part from genetic and biochemical heterogeneity.

Various nosologies and classification schema have been proposed over the past 200 years, but a numerical nosology has been widely used during the past 30 years (1). This grouped the various types of OI into five subgroups, OI types I–V, with the addition of a number of extremely rare syndromes. In an attempt to account for recent new insights into the pathogenesis of OI, the International Nomenclature Committee for Constitutional Disorders of the Skeleton (INCCDS) in 2010 proposed a descriptive clinical and molecular nosology for the groups (see Table 156-1) that combines molecular diagnoses with the former descriptive and numerical nomenclature (2).

The newer disorders are encompassed as subtypes of these five groups of disorders (see Tables 156-2–156-4). In addition to these syndromes, there are a large number of syndromes with osteoporosis and features in common with osteogenesis imperfecta, and a number of premature aging syndromes with overlapping clinical features.

### 156.2.1 Pathogenesis of Osteogenesis Imperfecta Syndromes

The vast majority of individuals with OI in European populations have mutations in collagen type I genes, either *COL1A1* or *COL1A2* (3). In other populations, such as in southern Africa, Southern Asia, or Samoa, evidence suggests that mutations in other genes may be more prevalent as causes of moderate to severe OI.

Collagen type I has a triple helical structure consisting of two  $\alpha 1$  chains and one  $\alpha 2$  chain. For the triple helix to fold correctly, every third amino acid residue must be a glycine, with the remaining amino acids rich in proline and hydroxyproline (3,4). The  $\alpha$ -chains are initially synthesized as pro- $\alpha$ -chains with polypeptide extensions at either end. The carboxy propeptide extension is essential for pro- $\alpha$ -chain association prior to triple helix assembly, which occurs in a carboxy to amino direction.

Four classes of COL1 mutation have been described (3): (1) those that reduce the amount of procollagen type I produced; (2) those that disrupt the triple-helical structure of procollagen type I—substitution of the glycine residue, small deletions or duplications, or exon skipping; (3) those that disturb chain association by alteration of the carboxy-terminal propeptide residues; and (4) those that reduce the amount of pro $\alpha 2$ (I), thus altering chain composition.

**TABLE 156-1** The Recommended Nomenclature of OI Syndromes INCCDS 2010

Syndrome Names <sup>a</sup>	Equivalent Numerical Type	Subtypes
Classic non-deforming OI with blue sclerae	I	2
Common variable OI with normal sclerae	IV	2
OI with calcification in interosseous membranes	V	1
Progressively deforming OI with normal sclerae	III	10
Perinatally lethal OI	II	5

<sup>a</sup>The syndromes are listed roughly in order of increasing severity of fracture tendency and skeletal deformity.

Using COL1 mutation analysis alone, it is difficult to make genotype/phenotype correlations in OI. In general, however, mutations resulting only in a quantitative defect in collagen type I production result in a milder phenotype than those leading to a qualitative defect (3,5). The most predictable outcome is from premature termination of transcription, which results in mRNA instability, reduced procollagen type I production, and a mild OI type I phenotype. Most instances at the molecular level are the result of nucleotide deletions that result in a frameshift in transcription and premature termination at a new stop codon. In such cases, normal collagen type I chains are produced, but the amount of collagen is reduced.

The phenotypic outcome of glycine mutations in the triple helix is less certain (5). In an attempt to link disease severity with the site and type of glycine mutation, severity rules have been formulated. *The chain rule*: a glycine mutation in  $\alpha 1$ (I) would result in a more severe phenotype than an equivalent mutation in  $\alpha 2$ (I) because there are twice as many  $\alpha 1$ (I) chains; *the position rule*: a glycine mutation nearer the carboxy-terminus of either  $\alpha 1$ (I) or  $\alpha 2$ (I) would disturb the triple helix formation more than the equivalent mutation nearer the amino terminus and result in a more severe phenotype; *the substitution rule*: a charged amino acid (aspartic acid, glutamic acid, or arginine) or a large amino acid (tryptophan) substitution of glycine would have a more severe consequence than small neutral amino acid (alanine or serine) substitution, because they cause the greatest alteration to the configuration of the triple helix. Numerous exceptions to the severity rules have been noted. This is in part because the two assumptions upon which these rules were based—that each segment of the Gly-X-Y repeat of the  $\alpha$ -chains has an equal role in triple helix formation and stability, and that the stability of mRNA, procollagen, and collagen were similarly effected by different mutations—do not hold true in all circumstances. This led to the formulation of the regional model, which suggests that at certain positions within the collagen triple helix there is

mutation tolerance that results in a less severe phenotype than would otherwise be expected (6). It is also clear that less severe phenotypes can arise from increased mRNA or protein degradation, with a resultant decrease in the amount of mutant collagen.

Apart from glycine, type I collagen proteins are rich in proline and lysine. Proline residues are hydroxylated at the 4' position, except for proline 986 in collagen α1(I)

and proline 707 in collagen α2(I), which are hydroxylated at the 3' position (7). The extent of 3' hydroxylation of these proline residues is directly correlated with the amount of type I collagen secretion, so that deficiency states result in a wide spectrum of phenotypic expression of OI ranging from Perinatally Lethal OI type II through severe Progressively Deforming type III. Prolyl 3-hydroxylation in the 3' position is carried out by a multiprotein

complex consisting of prolyl-3-hydroxylase 1 (leprecan) (8), cartilage-associated protein (CRTAP) and peptidylprolyl isomerase B (PPIB), which is also known as cyclophilin B (9,10).

Defective lysyl hydroxylation resulting from mutations in procollagen-lysine, 2-oxoglutarate S-dioxygenase 2 (PLOD2) results in the syndrome of OI and congenital joint contractures, or Bruck syndrome type 2 (11).

Recently, five further genes whose products play a role in type I collagen trafficking have been implicated in the pathogenesis of autosomal recessive types of OI, including *FKBP10* (12), serpin H1 (coding for HSP47) (13), and serpin F1 (14,15). *SP7/OSX* (osterix) (16) is a novel gene, not yet shown to have a role in collagen trafficking.

The majority of molecular studies into collagen type I have utilized skin fibroblasts. Little work has been performed using osteoblasts, which may differ from fibroblasts in respect to post-translational modification of mutant collagen and the incorporation of abnormal collagen molecules into the extracellular matrix of bone (17). Furthermore, other matrix proteins such as proteoglycans, hyaluronan, decorin, fibronectin, and thrombospondin may be abnormally expressed in osteoblasts with a mutation of collagen type I, further modifying the phenotype. The molecular pathology of the specific OI types is discussed below.

The organic abnormalities described above also result in disruption to the inorganic (mineral) phase of OI bone. Human OI bone has a higher average mineralization density than normal bone, and the murine model of moderate to severe OI (OIM mouse) has smaller and less well aligned mineral crystals than the wild-type mouse (18). It is the combination of the organic and inorganic abnormalities of OI bone that alters its biomechanical properties and makes it brittle. On an organic level, OIM mouse collagen has reduced tensile strength compared to its wild-type counterpart (19).

Somewhat surprisingly, OI bone is harder than normal bone, with an increased material density. Despite this, it breaks more readily and accumulates fatigue damage more easily. In addition, there is a reduction in the amount of bone in OI. Histomorphometric studies have shown a decrease in core width, cortical thickness, and trabecular number and thickness in OI bone (20). Individual osteoblasts produce a reduced amount of bone in OI, but owing to their increased number, the bone formation rate is increased. However, this does not lead to a net gain in bone mass, because osteoclastic activity is also increased. Together, these findings indicate a high turnover state with minimal net gain in bone mass. The increase in bone turnover is reflected in increased serum and urinary levels of markers of bone resorption (deoxypyridinoline and N-telopeptide) and bone formation (alkaline phosphatase and osteocalcin) (21). The reduction in core width seen on trans-iliac bone biopsies translates into thinner long bones with a reduced polar moment of inertia, further increasing the propensity to fracture.

## 156.3 MANAGEMENT OF OSTEOGENESIS IMPERFECTA

### 156.3.1 Densitometric Evaluation of Bone

Fracture frequency alone is unreliable for evaluating the efficacy of therapy in osteogenesis imperfecta, as the frequency of fractures varies widely from year to year in one patient and widely among patients. Its usefulness can be improved, however, by comparing the fracture frequency of radiologically confirmed fractures for the three years before treatment with that during treatment. Even so, it is necessary to combine this measure with other outcomes when evaluating therapeutic regimes. To this end, bone mineral density has frequently been employed. The assessment of bone density by standard X-ray films is highly dependent on a number of variables and is not reliably quantifiable. Thus, other investigative techniques, most notably dual-energy X-ray absorptiometry (DXA), have been employed to evaluate changes in bone density when subjects with OI were treated with therapeutic agents such as calcitonin and bisphosphonates.

DXA technology to assess bone mineral content and density in children with OI has been used increasingly over recent years. The skin entrance dose for total body, femur, and lumbar spine DXA is less than 50  $\mu$ Sv, which compares favorably with other investigative techniques and background radiation. However, the use and interpretation of DXA data in children, and especially those with OI, pose certain difficulties which must be taken into account.

There are two main measurements obtained when DXA is performed: bone mineral content (BMC) and bone mineral density (BMD). BMC represents the mass of mineral in the bone being evaluated and is measured in grams. BMD, as measured by DXA, does not represent the true volumetric density ( $\text{g}/\text{cm}^3$ ) of the bone, as would normally be measured in physics. Rather, it is the mass of bone mineral per projection area ( $\text{g}/\text{cm}^2$ ) and is given the term “areal BMD.” Areal BMD is a size-dependent measure. Shorter children therefore have a reduced areal BMD compared to age-matched controls, not because there is anything abnormal with the composition or structure of their bones, simply that the bones are smaller. Because the majority of children with OI have short stature, correcting for height when interpreting areal BMD is essential.

Further confounders that need to be considered are movement artifact from an uncooperative child, positioning difficulties due to spine and limb deformities, and erroneous projection areas due to excessively osteopenic bones.

Given these caveats, serial DXA measurements 6–12 months apart may be beneficial in evaluating bone mineral accrual in children with OI. In a growing bone, BMC and areal BMD should increase, therefore static

or decreasing values may indicate that an abnormality in bone development exists. Serial BMC and areal BMD assessment can also be used to evaluate the effectiveness of bone-specific interventions. Many therapeutic trials in OI (e.g. intravenous and oral bisphosphonates) assume that by increasing BMC and areal BMD bones are made stronger, and therefore have DXA measures as a primary outcome variable. It remains to be seen whether DXA data can successfully guide treatment decisions or duration. Research is also underway into the utility of peripheral quantitative computer tomography (pQCT) to evaluate the volumetric density of OI bone. At present, this method remains a research tool, but may prove valuable in clinical use.

### 156.3.2 Severity Grading in Osteogenesis Imperfecta Syndromes

Internationally agreed criteria for grading severity between affected individuals were proposed and adopted by the International Nosology group in 2009 (see [Figure 156-1](#)). They rely on clinical and historical data, fracture frequency, bone densitometry, and level of mobility. Confusion has resulted in the past because the numerical nomenclature of OI syndromes does not relate to severity but to the order in which the syndromes were identified and described.

### 156.3.3 Treatment of Osteogenesis Imperfecta

The aim of treatment in OI is to reduce fracture frequency and maximize mobility and other functional capacities (22). The optimal treatment approach involves an interdisciplinary team consisting of bone and mineral physicians, clinical geneticists, orthopedic surgeons, rehabilitation specialists, physiotherapists, and occupational therapists (22–24).

Despite optimal surgical and rehabilitative care, extreme bone fragility and deformity persists in many patients. Because of this, many treatments have been used in an attempt to improve bone quality and the quality of life of children and adults with OI. Albright, in 1981, reviewed 96 reports of 20 different treatments in OI, including hormones (calcitonin, cortisone, estrogen/androgen, growth hormone, parathyroid hormone, thyroxine, and thymus extract); vitamins A, C, and D; and minerals (aluminum, calcium, fluoride, magnesium, phosphate, and strontium); as well as arsenic, radiation, dilute hydrochloric acid, calf bone extract, and ovariectomized goat's milk. The majority of the authors reported a beneficial response to their treatment intervention. However, these therapies have fallen out of favor as none has delivered sustained benefit (25).

The major medical advance has come from the introduction of bisphosphonate therapy, and treatment with cyclic intravenous pamidronate or neridronate is now

viewed as the “gold standard” for the treatment of children and adults with OI of moderate to severe degree and its Cole–Carpenter and Bruck variants (26–29). To date, little data is available on the treatment of mild OI (two or fewer fractures per year, no vertebral crush fractures, and no long-bone deformities) or the use of oral bisphosphonates in OI. Bisphosphonates are potent antiresorptive agents that disrupt osteoclastic activity by interfering with the mevalonate pathway of cholesterol biosynthesis (30). Bisphosphonates bind avidly to the hydroxyapatite crystal of bone, which results in locally active concentrations within bone. While bound to the hydroxyapatite crystal, bisphosphonates are biologically inert. As bisphosphonate-containing bone is resorbed, the drug is released, once again becoming active against the osteoclast. This reservoir effect results in bisphosphonates having an extended half-life of many years.

### 156.3.4 Bisphosphonate Therapy for Children with Osteogenesis Imperfecta

The most extensively studied bisphosphonate in OI is Pamidronate®, a moderately potent amino-bisphosphonate. To date, the majority of published studies on bisphosphonate use in OI have been in children with moderate to severe disease, and all but one (31) have been observational in design.

The first reported use of a bisphosphonate in OI was in 1987, when Devogelaer et al. noted a “striking radiological and clinical improvement” in a 12-year-old girl treated for 12 months with oral pamidronate (32). It was not until 1998, however, that Astrom and Soderhall, and Glorieux et al. published systematic evaluations of cyclical intravenous pamidronate in children with severe OI (26,27). In summary, pamidronate in children with OI has been reported to decrease bone pain, enhance well-being, improve mobility and muscle strength, reduce fracture incidence, increase long-bone cortical thickness, increase vertebral size with vertebral reshaping, and increase bone mass and BMD. In an attempt to prevent growth disturbance and spine and limb deformity, cyclical intravenous pamidronate has also been used in babies and infants with OI (28). The treatment response in the younger children was more pronounced than in the older cohort, but further follow-up is needed to evaluate if function, growth, scoliosis, and limb deformities are improved. A multicenter international trial of the potent bisphosphonate zoledronate was carried out to assess its dosage, efficacy, and safety in OI compared to pamidronate. This study showed a similar response in terms of improvements in serial bone density and quality of life. An increased frequency of fracture was seen in the zoledronate treatment group, which may have been due to inclusion of some children with more severe OI. Zoledronate has the benefits of being able to be administered more rapidly and of having a longer dosing interval than pamidronate,

**(A) Mild Severity (of OI)**

- Annualized fracture rate of less than or equal to 1
- Straight long bones, i.e. no intrinsic long-bone deformity
- Minimal vertebral crush fractures
- Absence of chronic bone pain or minimal pain controlled by simple analgesics
- Normal or near-normal growth velocity and height
- Fully ambulant other than at times of acute fracture
- Regular school attendance, i.e. does not miss school owing to pain, lethargy, or fatigue
- Lumbar spine bone mineral density z-score usually  $\geq -2.0$

Children with Mild OI most often have OI type I or IV

**(B) Moderate Severity (of OI)**

- Annualized fracture rate greater than 1
- Bowing of long bones related to immobilization for recurrent fractures
- Vertebral crush fractures
- Anterior bowing of legs and thighs
- Lumbar spine bone mineral density z-score  $\leq -2.5$ .
- Absent from school owing to pain more than 5 days per year

**(C) Severe Disease (Progressively Deforming OI)**

- Progressive deformity of long bones and spine (unrelated to fractures)
- Multiple vertebral crush fractures
- Marked impairment of linear growth
- Cases intermediate between severe and extremely severe have few rib fractures but crumpled long bones

**(D) Extremely Severe Disease**

- Thighs held in fixed abduction and external rotation with limitation of movement of most joints
- Clinical indicators of severe chronic pain (pallor, sweateness, whimpering or grimacing on passive movement)
- Continuously beaded ribs due to multiple fractures before birth
- Crumpled (concertina-like) long bones
- All vertebrae hypoplastic/crushed
- Respiratory distress leading to perinatal death
- Perinatally lethal course

**FIGURE 156-1** Showing patients representative of levels of severity. (A) Mild severity—girl aged 7 years with OI but no skeletal deformity; (B) Moderate severity—girl aged 4 years after 12 months therapy with bowing right leg; (C) Severe—teenage male aged 14 years; (D) Extremely severe/perinatally lethal.

both of which may prove advantageous to patients and health-care facilities.

There is growing interest in the utility of oral bisphosphonates in OI. In a placebo-controlled trial of oral Olpadronate® in 34 children with OI (16 olpadronate), Sakkars et al. reported that olpadronate was associated with an increase in lumbar spine BMD, but did not improve muscle strength, mobility, function, or vertebral height (31).

A small randomized controlled study of the oral bisphosphonate risedronate showed an improvement in spine bone density and decrease in bone turnover, but no change in bone biopsy or pQCT data (33). A large multinational placebo-controlled trial is currently underway to further evaluate oral bisphosphonate use in mild OI. A large multicenter double-blind randomized placebo-controlled trial of alendronate in children with moderate to severe OI showed that while there was an improvement in bone density and decrease in bone turnover, there was no improvement in fracture rate, bone pain, vertebral height, bone histomorphometry, or physical activity with treatment (34). These data would suggest that, until there is data to the contrary, oral bisphosphonates should not be used in favor of intravenous bisphosphonates in children with OI. Oral therapy may, however, be of benefit as maintenance therapy in children with moderate to severe OI, or as initial therapy in mild OI. Studies are currently underway addressing both these issues.

Once bisphosphonates are stopped, they have little, if any, effect on new bone produced with growth and modeling. As such, it is usually necessary to give children with OI a maintenance dose of bisphosphonate following their acute treatment regimen. The best maintenance therapy is uncertain but is likely to be 30–50% of the acute treatment dose.

Histomorphometry has provided valuable insight into the actions of pamidronate in children with OI (35). The major effects of pamidronate were to increase cortical thickness and trabecular number. Trabecular thickness was not enhanced. Bone turnover was significantly reduced, with a decrease in both bone resorption and formation below that of age-matched normal controls. There was also an increase in residual calcified cartilage within the bone.

In adults with OI, pamidronate and a similar compound, neridronate, have been shown to increase spine and hip areal BMD and decrease fracture rates (36,37). The results in adults have not been as marked as those in children, suggesting that bisphosphonate therapy should be instigated during childhood to obtain maximal benefit.

The safety of bisphosphonate therapy continues to be of concern to many clinicians (38). To allow for this issue to be systematically evaluated, it is of paramount importance that children and adolescents only receive bisphosphonate therapy as part of well-run clinical trials. Pamidronate lowers serum calcium concentrations and this is most marked following the first infusion cycle (39). In

vitamin-D-replete individuals receiving the recommended calcium intake, the hypocalcemia is self-remitting. The majority of children have an acute phase reaction (fever, muscle pain, headache, and vomiting) 12–36 h following initial exposure to pamidronate. This appears to be due to a pamidronate-provoked release of osteoclast-specific interleukin 6, mimicking the type of febrile response seen from macrophage-released interleukin 6 in influenza (40). These side-effects can be minimized by the administration of acetaminophen (paracetamol) or the anti-inflammatory medication ibuprofen (41).

Infants with severe OI and pre-existing respiratory compromise have been reported to experience an acute respiratory distress in associated with the first pamidronate infusion (42). The etiology remains unclear, but may relate to cytokine release, hemodynamic compromise from fluid administration during the first infusion, or both. This report stresses the often fragile state of young children with severe OI and the need for close monitoring of this cohort during treatment.

Animal studies have shown that high-dose bisphosphonates can suppress growth, and concerns have been raised of this possibility in children. Counter to these concerns, Zeitlin et al. showed that pamidronate significantly improved the growth of children and adolescents with moderate to severe OI compared to historical controls over a 4-year treatment period, by preventing limb and spine deformity (43). In the same report, these authors noted rapid weight gain in a number of children with severe OI. The etiology of the weight gain remains unclear, but excessive weight could have a detrimental effect upon function and increase fracture risk. Transient uveitis occurs in approximately 1% of children who receive pamidronate (24).

As mentioned above, pamidronate suppresses bone turnover in children with OI to well below that of normal aged-matched controls (35). As highlighted recently, at high doses, pamidronate can interfere with bone modeling and result in undertubularization of long bones. In the growing skeleton, a reduction in bone remodeling results in the accumulation of mineralized cartilage within the bone, which contributes to the increase in bone density seen with pamidronate treatment (44). Further, acute reduction in remodeling and the persistence of calcified cartilage in bone account for the characteristic sclerotic metaphyseal lines seen on long-bone radiographs of children receiving pamidronate therapy (45).

Osteonecrosis of the jaw, or non-healing dental extractions, has emerged as a major issue in patients treated with high-dose or potent bisphosphonate (BRON). It was first reported by Marx in 2003 (46). It is most simply described as non-healing, painful jaw wounds following dental extraction or other dental procedures. At the present time, the risk from normal exfoliation of deciduous teeth in children is not quantified but presumed to be extremely small. Notwithstanding reports in adults, there has been no report of children treated with bisphosphonates long

term developing osteonecrosis of the jaw. A large study of 64 young people with OI from Sweden treated with bisphosphonates for up to 12 years revealed no instance of BRON (47). The risk of BRON in carefully supervised treatment of children is also believed to be very small.

Bisphosphonates are contraindicated during pregnancy, and all females of reproductive age should have a negative pregnancy test before each pamidronate treatment cycle or before commencing oral bisphosphonates. Because bisphosphonates persist in mineralized bone for many years, concern has also been expressed that bisphosphonates administered before conception could be released from the maternal skeleton during the pregnancy and affect the fetus (38,48). Munns et al. published a report in 2004 of two women with OI who became pregnant after 5 years of pamidronate therapy. No pamidronate was administered following conception. Both pregnancies went to term and there were no maternal complications noted. It could not be excluded, however, that the adverse events noted in the babies, hypocalcaemia and talipes equinovarus, were related to maternal pamidronate therapy (49). Clearly, further systematic follow-up of pregnancy outcome in this cohort is required and females should be counseled about the uncertainty surrounding this aspect of bisphosphonate treatment.

Other issues that can only be addressed through the continued systematic evaluation of bisphosphonate therapy in children and adults with OI are: the long-term benefits of treatment, the optimal treatment regime to maximize benefit and minimize potential long-term side-effects, and the outcome following cessation of therapy.

In summary:

- (1) Cyclic intravenous pamidronate has good short-term safety and efficacy in children and adolescents with moderate to severe OI and related disorders.
- (2) Pamidronate therapy should be offered to children with moderate to severe OI as defined by: two or more long-bone fractures per year, and/or vertebral crush fractures, and/or long-bone deformities, and/or children with OI type III or IV.
- (3) In severe cases, treatment can be started during infancy, but these children need to be monitored very closely, especially during the first infusion cycle.
- (4) Treatment continues to be effective in older teenagers and the upper age limit of responsiveness still remains to be defined.
- (5) Several dosage regimens appear to be effective:
  - (a) Low-dose frequent administration—0.5–1 mg/kg/month (50)
  - (b) High-dose infrequent administration—9 mg/kg/year, with a dose and treatment interval that varies with age (39).
- (6) All children treated with a bisphosphonate should be part of a well-run clinical trial. This will enable the safety and efficacy of these compounds to be adequately evaluated.
- (7) After completion of the acute treatment phase, most children will require ongoing maintenance therapy.
- (8) Further study is required before bisphosphonates can be administered to all patients with OI on the basis of low BMD alone.

### 156.3.5 Other Medical Therapies

Intermittent recombinant human parathyroid hormone (rhPTH) is a potent bone anabolic agent that increases bone mineral density and reduces vertebral fractures in postmenopausal and glucocorticoid-induced osteoporosis (51). By increasing bone formation, it was hoped that rhPTH could be a useful adjunct to bisphosphonate therapy. However, the occurrence of osteosarcomas in a significant proportion of treated young rats (52), and the possibility of this occurring in humans, has meant the risks of its use in children outweigh any potential benefit (53).

Recombinant human growth hormone (rhGH) has been shown to increase bone turnover in children with OI (54). As bone turnover is already increased in OI, any further increase may be detrimental to the bone health of these children. Antonazzi et al. reported that rhGH in combination with bisphosphonate increased BMD and growth compared to bisphosphonates alone (55).

Both bone marrow transplant (BMT) and gene therapy offer a cure for OI. Despite reported success from preliminary studies of BMT in children with severe OI (56,57), bone disease specialists remain skeptical of the benefit (58). As there is the potential for cure with BMT, it has been suggested that this therapy not be discarded, but that the basic science and technician details be thoroughly evaluated in animal models before further human studies are undertaken.

Many obstacles exist to successful gene therapy in OI. The most significant is the requirement to firstly knock out the abnormal collagen gene from which mutant molecules are synthesized that interfere with collagen macromolecular assembly and cause the most severe phenotypes; only then can the gene coding for the missing protein be replaced. It is encouraging to note that *in vitro* experiments have shown that hammerhead ribosomes (small RNA molecules that can cut mRNA in the absence of protein cofactors) can reduce the amount of mutant *COL1A1* mRNA by about 50% (59). This may be the first step on the path to a genetic cure for OI, but introduction of these therapies into the clinical setting remains some time off.

## 156.4 CLINICAL FEATURES OF THE OI SYNDROMES

### 156.4.1 Non-deforming Osteogenesis Imperfecta with Blue Sclerae—OI Type I

This type of OI is characterized by autosomal dominant inheritance of excessive bone fragility, which is usually associated with low bone mass, distinctly blue sclerae,

and susceptibility to conductive hearing loss commencing in adolescence and adult life. This is the most common type of OI and has a birth frequency in the order of 1:25,000 live births and a similar population frequency (60–62). In most European communities, the majority of people with OI have affected relatives. (Synonyms: Van der Hoeve syndrome, trias fragilitis ossium.)

**156.4.1.1 Clinical Features.** The sclerae are of a deep blue-gray hue and remain so throughout life. Fractures characteristically result from minimal trauma. Despite the tendency to bone fragility, accidental trauma does not always lead to fractures.

Opalescent dentine (OD), also known as dentinogenesis imperfecta (DI), is observed in some families with this trait but not others. OD produces a distinctive yellowing and apparent transparency of the teeth, which are often worn prematurely or broken. Some teeth with OD may have a particularly grayish hue. Radiologic study of these teeth shows that they have short roots with constricted corono-radicular junctions (see Figure 156-2).

**FIGURE 156-2** Classic osteogenesis imperfecta type I. Father and son both with numerous fractures, intensely blue sclerae, and mild shortening of stature. Father wears a hearing aid.

Paterson et al. (61) have shown that patients with OI type I and normal teeth differ from patients with OI type I with OD. The latter group is more likely to have fractures at birth (25% vs 6%) and have a higher fracture frequency, more severe short stature, and skeletal deformity. Both groups have a similar frequency of joint hypermobility, bruising, hearing loss, and joint dislocations.

When fractures occur at birth, these are usually only a few in number. Individuals with fractures at birth subsequently have no more deformity, handicap, or number of fractures than other individuals who have their first fracture after 1 year of age. Deformities of the limbs in this group are usually the result of fractures, but bowing, particularly of the lower limbs, is common and is associated with low bone mass. Some adults have progressive kyphoscoliosis, which may be of a severe degree. Kyphosis alone is common in older adults with OI type I, but rarely seen in children. There is usually excessive hypermobility in the small joints of the hands and feet, but this feature is less marked in adults (62). Some patients have marked hypermobility, and in clinical features, show significant overlap with the hypermobile type of Ehlers–Danlos syndrome. Adult patients with OI type I frequently suffer from chronic fatigue or fibromyalgia related to their hypermobility. Hearing impairment and vestibular dysfunction are troublesome complications (63,64).

There is a high frequency of arcus cornea in adults with OI type I. No other visual abnormalities are associated with OI. Patients with OI type I frequently have easy bruising (62), which in children may be mistaken for child abuse, when associated with unexplained fractures. Ankle sprains and dislocation occur rarely.

Bone densitometry determined by dual-energy X-ray absorptiometry falls into the low normal range in many children with OI type I. However, in late childhood and adolescence, areal bone density in the long bones and spine frequently may fall to two standard deviations below the mean.

Radiographic studies in most patients in this group show generalized osteopenia, evidence of previous fractures, and normal callus formation at the site of recent fractures. Deformities are usually the result of angulation at the site of previous fractures. However, bowing of the femora, tibiae, and fibulae and deformity in the bones of the feet, particularly metatarsus varus, are observed. Severe osteoporosis of the spine is rarely seen in these patients, and most have normally formed vertebral bodies with some wedging and flattening. Wormian bones are not necessarily present in the skull and are found in no more than 70% of subjects. Spontaneous improvement is observed during adolescence, with a marked reduction in the frequency of fractures. This reflects the resistance to fracture of larger-diameter long bones. There is exaggerated postmenopausal bone loss, and adults who have not had fractures for many years may commence having fractures again in their late 40s–50s.

**156.4.1.2 Genetics.** Inheritance is autosomal dominant with variable expressivity. Penetrance for fractures approximates 90% and for blue sclerae 100%. Hearing impairment is age related (63). Patients with OI type I and OD have earlier and more marked manifestations than those with OI type I and normal teeth, and this feature seems to be inherited within families.

**156.4.1.3 Molecular Pathology.** At the cellular (in vitro) level, these patients show approximately 50% reduction in synthesis of type I procollagen. The mutations are heterozygous, but there is no evidence for deletion of one or other allele. Post-translational modification of type I procollagen appears to be normal in contradistinction to all other forms of OI. The commonest mutational mechanism in OI type I is mutation arising from premature termination of transcription and translation (PTT) from one *COL1A1* allele, as a result of sense-to-nonsense mutation, out-of-frame deletions, or insertions that result in generation of a new stop codon downstream or splice mutations. *COL1A2* mutations are far less commonly encountered than *COL1A1* mutations (65,66).

**156.4.1.4 Differential Diagnosis.** *Blue sclerae and keratoconus:* In this autosomal recessive syndrome, blue sclerae are associated with keratoconus, middle ear bone conduction defect, joint hypermobility, and spondylolysis without liability to fractures (67).

#### 156.4.1.5 Management.

**156.4.1.5.1 Therapy.** Children and adults with OI type I have less tendency to progressive skeletal deformity than in other types of OI and thus they maintain better mobility. Serial bone densitometry should be possible as these patients have little skeletal deformity. If there are recurrent long-bone fractures or vertebral crush fractures in children and adults, cyclic intravenous pamidronate (see section 156.3.4 above) can be used with a very favorable response to therapy. A multidisciplinary approach to caring for these children and adults is also important because of the associated issues of joint hypermobility (occupational therapy), progressive hearing impairment, and vertigo (audiologist and ENT specialist). Where OD is present, 6-monthly dental reviews should be undertaken. It may be valuable to monitor the clinical state and bone density in adult women planning a pregnancy before and immediately after the pregnancy. Given the caveats discussed above, it may be advisable to institute therapy following delivery with a bisphosphonate for those women whose pregnancy-related bone loss has resulted in symptomatic osteopenia and/or reduced bone mineral density that falls into the symptomatic/fracture range.

**156.4.1.5.2 Genetic Counseling and Prenatal Diagnosis.** For an affected adult mating with a normal partner, there is a 50% chance of an affected child. Where two adults with OI type I mate, there is a 25% chance for a homozygous affected infant, which is likely to be perinatally lethal or severely affected. Ultrasound

and radiographic studies prenatally will occasionally differentiate a normal from an affected fetus. Prenatal prediction of OI type I is feasible when a specific mutation has been identified. Preimplantation genetic diagnosis has been reported (68).

### 156.4.2 Common Variable Osteogenesis Imperfecta with Normal Sclerae—OI Type IV

OI type IV is characterized by osteoporosis leading to bone fragility without the characteristic features of the OI type I syndrome (i.e. blue sclerae and early onset deafness) (69). See Figure 156-3. (Synonyms: Ekman-Lobstein disease, osteopsathyrosis idiopathica.) There are many families found to be affected in population studies of OI and there is phenotypic overlap with osteoporosis resulting from other causes.

**156.4.2.1 Clinical Findings.** The sclerae may be bluish at birth but become progressively less blue as the patient matures. Adults usually have normal sclerae and there is no tendency to develop arcus cornea. These individuals have variable ages of onset of fractures, which may be present at birth (approximately 25%) or may not occur until adult life. Significant bowing of the lower limbs has

**FIGURE 156-3** Common variable osteogenesis imperfecta type IV. Patient aged 2 years (not walking) with mild bowing of the lower limbs and sclerae of normal hue; her father is similarly affected.

been present at birth as the only feature of this syndrome. Some patients improve with age in that bowing lessens. Just as in OI type I, these patients appeared to show a spontaneous improvement at the time of puberty, and generally fewer fractures are encountered in adolescents and adults. However, the large majority of patients have short stature of postnatal onset and measurement of bone density by DXA may reveal persistent osteopenia (62,70).

A small proportion have severe progressive deformity of lower limb bones and spine that is out of proportion to their severity as judged by fracture frequency. It is clear that this is mainly the result of progressive osteoporosis and can be prevented by early institution of bisphosphonate therapy. Those so affected show more skull deformity and more severe short stature.

Opalescent dentine has been observed in some families and not others, suggesting OI type IV should be divided into two subgroups: OI type IV with normal teeth, and OI type IV with OD, which is associated with a greater frequency of fractures, and more fractures at birth.

Hearing impairment and vestibular dysfunction, although less frequent than in patients with non-deforming OI and blue sclerae, are troublesome complications. These complications are discussed in detail at the end of this section.

Radiographically, this group is defined by generalized osteopenia. Although multiple fractures may be observed in the skeleton at birth and throughout life, as a group, these patients have less osteopenia and fewer fractures than infants with OI type III. The skull does not always show multiple Wormian bones, which are absent in 30–50% of subjects. This group has an increased frequency of progressive deformity of the skull base, known as basilar impression. The presence of OD is associated with a five times increase in risk of basilar impression (71).

**156.4.2.2 Genetics.** Inheritance is autosomal dominant. As in OI type I, families are observed either with normal teeth or with OD.

**156.4.2.3 Molecular Pathology.** Mutations recognized to date in OI type IV have been evenly distributed between *COL1A1* and *COL1A2*. These mutations, which are usually missense mutations in the glycine residues, reduce collagen triple helix formation and stability and thus presumably reduce the amount of collagen available for bone formation (3,72).

#### 156.4.2.4 Differential Diagnosis.

(1) *Juvenile idiopathic osteoporosis (IJO)*: IJO is a rare, self-limiting disorder that may be difficult to distinguish from mildly affected cases of OI type IV (with normal teeth). Features of IJO not associated with OI are: onset of symptoms 2–3 years prior to the onset of puberty and usually self-remitting. In addition, there is a negative family history, metaphyseal fracture, neo-osseous ossification, straight long bones with normal cortical thickness, no extra-skeletal manifestations as in OI, and decreased bone turnover.

Osteopenia in IJO is most marked in the axial skeleton (73). All patients in this group should be investigated for mutations in *LRP5* (74).

(2) *Osteogenesis imperfecta with calcification in interosseous membranes*: People with OI type V also have normal sclerae (75).

(3) *Other Mendelian disorders and inborn errors of metabolism characterized by osteopenia*: Osteopenia is usually also a feature of progeria (Hutchinson–Gilford syndrome) an autosomal dominant disorder; Winchester, Cockayne, and Rothmund–Thompson syndromes; and Fanconi pancytopenia; all autosomal recessive syndromes. It is also frequently recognized in homocystinuria, methylmalonicacidemia, dibasic aminoaciduria, prolidase deficiency, glycogen storage disease type I, Menkes syndrome, and Lowe oculocerebrorenal syndrome.

(4) A number of autosomal recessive syndromes (see Table 156-4) are complicated by osteoporosis and may present because of osteoporosis-related complications.

#### 156.4.2.5 Management.

**156.4.2.5.1 Monitoring.** Regular monitoring of fracture frequency and bone densitometry by DXA is useful to predict the need for bisphosphonate therapy. Screening for basilar impression for practical purposes can be commenced after 5 years (71). If not present then screening can be repeated every 3 years. When basilar impression is detected, annual monitoring for progression is indicated. Audiology should be undertaken from early adolescence onwards.

**156.4.2.5.2 Therapy.** Treatment is as for OI in general. Where there are recurrent long-bone fractures, vertebral crush fractures, or skeletal deformity, cyclic intravenous pamidronate should be offered as the first line of treatment. The response in OI type IV is particularly good. In osteopenic but asymptomatic children with BMD  $\leq 2.0$  SD for age, one can make the case to treat before the first vertebral or femoral fracture occurs, as the immobilization following a fracture in an osteopenic OI child is usually worsened and can rarely be reversed by physical activity alone. Further studies are required before this approach can be routinely recommended. Where dentinogenesis imperfecta is present, 6-monthly dental reviews should be undertaken.

**156.4.2.5.3 Genetic Counseling and Prenatal Diagnosis.** For the offspring of an affected parent and normal parent, there is a 50% chance of affected offspring. Ultrasound prenatal diagnosis is unlikely to be definitive, although fractures and leg bowing may be detected in the third trimester. Prenatal prediction of OI type IV has been achieved by direct sequencing when a specific mutation has been identified. Preimplantation genetic diagnosis has been reported in OI type IV (68).

### 156.4.3 Osteogenesis Imperfecta with Calcification in Interosseous Membranes—OI Type V

OI type V is a moderate to severe bone fragility disorder, and accounts for approximately 5% of individuals with OI seen in the hospital setting and up to 10% with severe to moderately severe OI (76). Calcification (possibly ossification) of the interosseous membrane in the forearms and the legs commences early in life (Figure 156-4). This leads to restriction of pronation and supination, and eventual dislocation of the radial heads (75,77,78). The sclerae are white, and OD and Wormian bones are not present. Those affected tend to have higher serum alkaline phosphatase values and have an increased risk of developing hyperplastic callus following a fracture or orthopedic surgery. Rarely, the hyperplastic callus has been mistaken for an aggressive osteosarcoma of bone.

Familial recurrence is consistent with autosomal dominant inheritance (75).

This disorder was first recognized as a separate entity 90 years ago and has been known as the “hyperplastic callus” type of OI. These subjects have ossification in the interosseous ligaments, and it is now accepted that this latter feature is the most penetrant feature and that many affected individuals do not develop hyperplastic callus. This disorder has a distinct pattern of bone histomorphometry with coarse mesh-like lamellation, which distinguishes it as an entity from OI type IV.

Hyperplastic callus following long-bone fracture is a frequent finding in patients with OI type V. On occasion, a massive callus develops, leading to swelling and pain at the site of the fracture, which can mimic osteosarcoma but may be distinguished from it on magnetic resonance imaging (MRI) and computerized tomography (CT). Its progress may be prevented by the prompt use of indomethacin, an anti-inflammatory prostaglandin inhibitor. Collagen studies exclude the involvement of type I collagen genes.

#### 156.4.3.1 Management.

**156.4.3.1.1 Therapy.** Treatment is as for OI in general. Where there are recurrent long-bone fractures, vertebral crush fractures, or skeletal deformity, cyclic intravenous pamidronate should be offered as the first line of treatment. As with OI types III and IV, OI type V

responds well to cyclical intravenous pamidronate (79). Anti-inflammatory medication is of benefit to reduce the severity of hypertrophic callus development. An overuse syndrome in the shoulder abductors frequently results from the need to abduct the shoulders to achieve pronation of the hands. Consultation with an occupational therapist is important to minimize the disability arising from the upper limb and shoulder symptoms.

**156.4.3.1.2 Genetic Counseling.** For the offspring of an affected parent and a normal parent, there is a 50% chance of being affected. Until the causative mutation is identified, prenatal diagnosis remains problematic.

### 156.4.4 Progressively Deforming Osteogenesis Imperfecta with Normal Sclerae—OI Type III

Progressively deforming OI was originally characterized by autosomal recessive inheritance of usually non-lethal OI with severe bone fragility leading to progressive deformity of the skeleton and usually light blue or normal sclerae (80) (Figure 156-5). Because the “progressively deforming OI” phenotype is not specific to this form of OI, individuals with those forms of OI with moderately severe expression and fresh heterozygous mutation in type I collagen genes have been classified in this group in addition to multiple recessive disorders. The group is subdivided into two subgroups:

- (1) OI type III—autosomal dominant
- (2) OI type III—autosomal recessive types.

For practical purposes, at the present time these are phenotypically indistinguishable and the distinction is made on unequivocal pedigree grounds or on molecular genetic evidence.

**156.4.4.1 Clinical Features.** These individuals have newborn or infant presentation with severe bone fragility and multiple fractures leading to progressive deformity of the skeleton. They are generally born at or near term and have normal birth weight and often normal birth length, although this may be reduced because of deformities of the lower limbs at birth. Fractures are present in most cases at birth and occur frequently during childhood. Although the sclerae may be blue at birth, observation of many patients with this syndrome reveals that

**FIGURE 156-4** Osteogenesis imperfecta type V. Plain radiograph of forearm showing ossification extending into the interosseous ligament from the medial borders of the radius and ulna.

the sclerae become progressively less blue with age. The presence of clubfeet at birth should raise the possibility that the child has one of the Bruck syndromes or that the disorder is due to homozygous mutations in *FKBP10*. All patients have poor longitudinal growth and fall well below the third percentile in height for age and sex. Progressive kyphoscoliosis develops during childhood and progresses into adolescence. Hearing impairment has not been reported in children with this syndrome. Hearing loss has been variously reported in 16–80% of adults. In view of the severe osteopenia and liability to fractures, it is likely that there is significant involvement of the ossicular chain, leading to hearing defect. OD is a variable feature.

At birth, there is usually overmodeling of the shafts of the long bones, with widening of the femoral metaphyses and angulation of the tibiae. There is generalized osteopenia and multiple fractures. Within weeks to months, in most infants, the shafts of the long bones show undermodeling, producing a “broad-bone” appearance. From several years of age, progressive disruption and repair of osseous trabeculae in the metaphyses may produce a “popcorn” appearance similar to that seen in various forms of enchondromatosis. The ribs are thin, osteopenic, and progressively crowded as platyspondylia increases. The skull shows multiple Wormian bones, although these may not be evident until several weeks to months of age.

In the past, approximately only one-third of the patients survived long term, reflecting not only the severity of the disorder but also the heterogeneity within the group. Death usually resulted from the complications of severe bone fragility and skeletal deformity, including kyphoscoliosis, pulmonary hypertension, and cardiorespiratory failure. Given the present therapeutic options, specifically treatment with cyclic intravenous pamidronate commenced in infancy, it can be expected that the majority of patients with OI type III will survive into adult life. Furthermore, early institution of

bisphosphonate therapy results in less skeletal deformity and more normal growth.

#### 156.4.4.2 Genetics.

**156.4.4.2.1 Autosomal Dominant OI Type III.** The great majority of cases of OI type III in North America and Europe are dominantly inherited and result from heterozygous missense mutations in type I collagen genes (3,5). Sibling recurrence results from parental germinal cell mosaicism, so that an empiric recurrence risk of approximately 6% should be given (81).

**156.4.4.2.2 Autosomal Recessive Forms of OI Type III.** Autosomal recessive forms may be the commonest cause of OI in black Africans (82). In North America it is estimated that 15% of children with a phenotype with severe progressive deformity result from autosomal recessive inheritance. There is some evidence that there are regional differences in the prevalence of distinct autosomal recessive disorders between western and southern African populations. In eastern Mediterranean and Pakistani patients affected with OI, recessive inheritance has been confirmed at the molecular level in a high percentage of those affected. Recurrence in siblings and parental consanguinity point to autosomal recessive inheritance except in populations such as western and southern Africa and Samoa, where there is a high heterozygote frequency for recessively inherited types of OI.

#### 156.4.4.3 Molecular Pathology.

- Autosomal dominant OI type III

Heterozygous missense mutations account for the majority of cases of OI type III in European populations. These mutations predominantly involve the first glycine of the Gly-X-Y repeat and result in delayed triple helical assembly. This is associated with increased degradation of type I collagen polypeptides. The bone pathology results from an excess of bone turnover and abnormal bone architecture (see section 156.2.1).

- Autosomal recessive forms of OI type III

Homozygous or doubly heterozygous mutations in at least nine genes have been shown to result in a pattern of OI with progressive deforming of long bones, spine, or pelvis (protrusio acetabulae).

- *COL1A1* and *COL1A2* mutations

In one well-documented child with OI type III born to normal but consanguineous parents, the collagen gene mutation, a 4-nucleotide frameshift deletion, alters the pro $\alpha$ 2(I) chains, which are not incorporated into the collagen triple helix. The collagen present in tissues such as bone and skin was composed of  $\alpha$ (1)I trimers (83).

However, there had been very few reports of homozygosity for mutations in *COL1A1* or *COL1A2* during some 35 years of research into type I collagen mutations in OI, but many reports of pedigrees pointing to autosomal recessive inheritance. During the past 10 years, eight further genes have been characterized in which

**FIGURE 156-5** Progressively deforming osteogenesis imperfecta type III. A 14-year-old boy with severe short stature and progressive deformity of long bones and spine.

mutations result in either perinatally lethal and/or severe OI (84) (Tables 156-2 and 156-3).

- Genes regulating 3'-prolyl hydroxylation

Three of these genes code for a protein which comprises one of the three components of the multiprotein enzymatic unit responsible for prolyl 3-hydroxylation. These are *LEPRE1*, coding for prolyl-3-hydroxylase (8); *CRTAP*, coding for cartilage-associated protein (7); and *PPIB*, coding for peptidyl-prolyl isomerase B (10). *CRTAP* and *PPIB* proteins have chaperone functions and it is therefore interesting to note that the proteins encoded by *FKBP10* (coding for FK506-binding protein) and *SERPINH1* (coding for the collagen chaperone protein HSP47) also have important collagen chaperone functions. There is some variability in the severity of phenotypes.

- *FKBP10*, coding for FK506-binding protein

Approximately 4% of children with moderately severe OI with normal scleral hue and normal teeth have a phenotype previously known as OI type VII, characterized by a distinctive pattern of bone histomorphometry with excessive osteoid on the trabecular margins and a “fish-scale-like lamellar” appearance on polarized light examination. These patients, previously designated OI type VI in Online Mendelian Inheritance in Man (OMIM), have the identical phenotype to patients described in a large Turkish kindred discovered to have a mutation in the *FKBP10* gene, a molecular chaperone coding for FK506-binding protein, which has peptidyl-prolyl isomerase activity (12). Subsequently, mutations in *FKBP10* were shown to be common in the Saudi Arabian, southern African, and Samoan populations (85,86), where OI may manifest as congenital clubfeet and progressive protrusio acetabulae in young adult life.

- Serpin H1 and serpin F1

Severe progressively deforming OI phenotypes result from mutations serpin H1, coding for heat shock protein 47 (HSP47) (13). Mutations in serpin F1 result in a phenotype previously known as OI type VI (14). Both these genes encode important chaperone functions for type I collagen polypeptide modification and processing in the endoplasmic reticulum prior to secretion.

- Osterix (OSX)

A further form of OI with autosomal recessive inheritance has been reported in an Egyptian proband with moderately severe OI. This results from mutations in *OSX*, which encodes an osteoblast-specific transcription factor SP7/*OSX*, which belongs to the specificity protein (Sp) subgroup of the Kruppel-like family of transcription factors. In mice, *Osx* is essential in regulating the differentiation of preosteoblasts to osteoblasts and operates downstream from *RunX2* in the mouse. Mutations in *RUNX2* in humans result in cleidocranial dysplasia,

where there is also a propensity to fracture in some patients (16).

- *BMP1* and carboxy-terminal procollagen cleavage

Homozygous mutations in bone morphogenetic protein (gene *BMP1*), responsible for cleavage of the carboxy-terminal peptide of type I collagens, have also been reported to result in a severe progressively deforming OI phenotype. This patient had increased bone density but none of the features of an osteopetrotic bone disorder. The mutation interferes with processing in type I collagen fibrillogenesis (87).

#### 156.4.4.4 Differential Diagnosis.

- (1) *OI type II*: There is an overlap in phenotypic severity with infants with OI type II, but infants with OI type III usually have better ossification of the skull and the hips are not usually held in fixed abduction and external rotation.
- (2) *Severe OI type I and type IV*: As infants with OI type III are severely affected, phenotypic features alone at birth do not allow distinction from other severely affected infants with OI type I or OI type IV. Patients with OI type I and IV with OD are more likely to have fractures at birth (25%) and short stature with deformity of long bones and spine. Family history and natural history of skeletal radiographic abnormalities are the features by which these patients may be distinguished from other cases with a progressively deforming phenotype with blue (type I) or normal sclerae (type IV). However, novel genetic mechanisms such as double heterozygosity or isodisomy should be considered when considering recurrence risk.
- (3) *Cole-Carpenter syndrome*: This syndrome is characterized by severe bone fragility and metaphyseal and rib fractures similar to those seen in non-accidental injury. In addition, there is proptosis, craniosynostosis, and prominent vascular markings over the anterior cranium (see below).
- (4) There are many other rare syndromes with osteoporosis that must be distinguished from OI type III (see Table 156-4).

#### 156.4.4.5 Management.

**156.4.4.5.1 Therapy.** Intensive rehabilitation and orthopedic care should be instituted to prevent progressive deformity and provide for as normal a development as possible. This is best delivered in a center of expertise by a multidisciplinary team or in consultation with a regional team. Intramedullary rodding may improve mobility and prevent fractures, and is also used to correct and prevent progressive deformity. Various orthoses can be provided or designed that assist in the rehabilitation of these children; these orthoses improve mobility and normalize activities of daily living. Cyclic intravenous pamidronate has been used in children with OI type III resulting in decreased fracture frequency, increased mobility, and improved quality of life and should be

offered from infancy. In centers of expertise, consideration should be given to commencing therapy in the first year of life. Where dentinogenesis imperfecta is present, 6-monthly dental reviews should be undertaken (88).

### 156.4.5 Perinatally Lethal Osteogenesis Imperfecta Syndromes—OI Type II

OI type II is characterized by extreme bone fragility, leading to intrauterine or early infant death. The group is clinically and biochemically heterogeneous (89–91). Three subgroups useful for prognostic counseling are distinguished on a radiographic basis: (1) subgroup with continuously beaded ribs and crumpled long bones (see Figure 156-6); (2) similar long bones but relatively normal ribs with few if any rib fractures; and (3) long, narrow dysplastic but beaded ribs with inadequately modeled long bones and multiple fractures. Collagen and DNA studies show that within each subgroup there is further biochemical and molecular heterogeneity.

Babies in each of the three subgroups have been demonstrated to have abnormal brain neuropathology consisting of perivenous microcalcifications and impaired neuroblast migration and periventricular leukomalacia (92). Of seven babies with OI type II, only one fell into

subgroup C, but that baby had hippocampal malrotation as well as the abnormal features seen in babies with the other types of OI type II.

#### 156.4.5.1 Clinical Features.

- Subgroup A

Affected infants are commonly premature, and except where hydropic, with mean birth weight and birth length less than the fiftieth percentile for gestation (89). One-fifth are stillborn, and the remainder die within hours or days of birth (90% deceased by 4 weeks). General connective tissue fragility is present, and dismemberment may occur during delivery.

The thighs are characteristically held in fixed abduction and external rotation (see Figure 156-6), the chest is small, and limbs are markedly short and frequently angulated and bowed. The cranium often appears disproportionately large for the face, and there is commonly mild micrognathia with a small narrow nose. Dark blue sclerae are present in virtually all those affected.

Radiographic study shows a small thorax with slightly shortened ribs, which are thickened with continuous beading or wavy contours. The femora appear broad and rectangular with fine wavy margins (like a concertina) or are broad, undermodeled, and very hypoplastic. Long and short tubular bones are demineralized, shortened, and sometimes crumpled with multiple fractures. The tibiae are usually angulated. Vertebrae appear flattened and hypoplastic to a variable degree. The skull and face show diminished mineralization and multiple ossification centers (Wormian bones) throughout the calvaria. The pelvis is hypoplastic, with flattening of acetabular roofs and iliac crests.

- Subgroup B

Subgroup B patients appear phenotypically similar to subgroup A at birth, but death from respiratory failure is not as likely. Survival for weeks to months and even years is observed (89). Radiographically, the ribs are shortened with few or no fractures. The long bones are broad and crumpled (accordion-like) as in subgroup A. In those infants who survive the newborn period, a typical broad bone appearance develops in the first few weeks of life.

- Subgroup C

Subgroup C syndrome is extremely rare. All babies have been very small for gestational age and were stillborn or died in the newborn period (81). Skeletal radiographs show slender, not so uniformly beaded ribs, slender long bones with fractures, twisting of the shafts of the femora, and angulation deformities. There is extreme demineralization of the skull and face.

**156.4.5.2 Genetics.** It is now clear from collagen biochemical and DNA studies that sibling recurrence in the majority of families of western and Central European

**FIGURE 156-6** Osteogenesis imperfecta type II. Stillborn infant showing short, deformed limbs with broad thighs fixed at right angles to trunk, and relatively large head.

background can be explained by parental germline mosaicism. At least 18 such pedigrees have been identified (3). Furthermore, clinical and molecular investigations suggest that in most of such families, one or other parent can be shown to have mild features of OI due to high-level somatic mosaicism (93).

True autosomal recessive inheritance is common in a number of populations, but the phenotype will often be similar to the second prognostic group (B) with less severe involvement of ribs yet nevertheless a high perinatal mortality (8,84).

Where the proband has findings of subgroup B, the empiric recurrence risk in a United Kingdom population was 7.7% (81), presumably reflecting the mixture of historic European and immigrant populations from areas with a high risk of consanguinity. The finding of sibling recurrence in association with consanguinity confirms that a proportion of cases arise from autosomal recessive inheritance.

Subgroup C may represent an autosomal recessive disorder based on the observation of sibling recurrence and parental consanguinity (89), although few cases have been reported and a genotype correlation has not yet been established.

**156.4.5.3 Molecular Pathology.** OI type II, like OI type III, is genetically heterogenous. Generally those babies with a phenotype that conforms to the subgroup A with continuous fractures of the ribs, studied at the biochemical or DNA level, have been shown to have mutations in type I collagen genes, both *COL1A1* and *COL1A2*. Diminished production of type I collagen results from abnormal intracellular processing, and abnormal type I collagen is found in their bone (3,8,84). The majority of mutations in *COL1* genes in these cases have been heterozygous. The most common mutations are missense and occasional multi-exon deletion mutations in the helical domain of type I collagen genes and rarely mutations in carboxy-terminal propeptides. The substitution rules apply (3,4). These mutations disrupt triple helical assembly of the two type I collagen polypeptides. Point mutations in glycine codons, such as glycine to cysteine, which lead to disulfide bridging, and glycine to arginine substitutions, disrupt helix formation. Delayed triple helical assembly results in overmodification of type I collagen pro $\alpha$ 1(I) and pro $\alpha$ 2(I) polypeptide chains which are prematurely degraded. Severe tissue collagen deficiency leads to structurally weak bone and skin. The skeleton is progressively crushed and broken by uterine contraction during intrauterine life.

In families where the phenotype conforms more to the subgroup B pattern with a paucity of rib fractures, homozygous or doubly heterozygous mutations in genes resulting in defective prolyl 3-hydroxylation have frequently been encountered. Thus, the most commonly encountered mutations are in *LEPRE1*, *CRTAP*, or *PPIB* (84,90). Despite the high perinatal lethality, there are occasional long-term survivors who can be grouped

with those patients with OI type III. Here we observe a continuum of phenotypes.

#### 156.4.5.4 Differential Diagnosis.

- (1) *OI with microcephaly and cataracts*: This syndrome has clinical and radiographic features similar to OI type II, but all affected have microcephaly and cataracts (94). On the basis of sibling recurrence, autosomal recessive inheritance was postulated, but germinal mosaicism in a parent for a contiguous gene deletion might also explain the pedigree.
- (2) *OI type III*: The distinction between these two syndromes is based on the clinical and radiographic findings at the time of birth. In OI type III, the femora do not show a crumpled concertina appearance at birth. Infants with OI type II, from the second severity subgroup, who survive to several months of age will show skeletal radiographic findings indistinguishable from OI type III at that time.
- (3) *Neonatal hyperparathyroidism*: Both primary and secondary neonatal hyperparathyroidism may result in rib and long-bone fractures. Periosteal cloaking (subperiosteal calcification) should be distinguished from the crumpled accordion-like appearance of long bones in OI type II (95).
- (4) *Infantile cortical hyperostosis (perinatal form)*: The clinical and radiographic findings in the infantile cortical hyperostosis (Caffey disease) should be distinguished from OI type II, although thickening of ribs and beading and thickening of the long bones is frequently confused (see below). One form of infantile cortical hyperostosis results from a specific mutation, R836C, in *COL1A1* (96).

#### 156.4.5.5 Management.

**156.4.5.5.1 Therapy.** Therapeutic intervention will not usually lead to survival. An occasional infant with milder subgroup B disease will survive and require intensive management (see OI type III, section 156.4.4.5). In general, infants with perinatally lethal crumpled bone OI should not be treated with cyclic intravenous pamidronate because survival is very unlikely despite therapy and there is a high likelihood of non-skeletal complications such as neurologic involvement.

**156.4.5.5.2 Genetic Counseling and Prenatal Diagnosis.** When possible, recurrence risks following a single case of OI type II in a family are approximately 6–7% (81). However, certain populations have an increased prevalence of autosomal recessive forms of perinatally lethal OI, and these include west African and south Asian populations where there is a higher rate than usual of parental consanguinity. Byers et al. (1988) have studied 65 complete families of OI type II and found an empiric recurrence risk of approximately 6% (97). This may reflect an admixture of these rare recessive forms as well as families where there is germline mosaicism for heterozygous mutations. Serial ultrasound studies from the fourth to fifth gestational month are indicated in all

future pregnancies, with a high likelihood of diagnosis of OI type II based on limb shortening, fractures, or polyhydramnios (98).

In families with one or more previously affected offspring, direct DNA analysis on chorionic villus biopsy tissue may be performed in subsequent pregnancies when a DNA mutation has been detected in a previously affected infant. Commercial testing for type I collagen structural mutations as well as for mutations in the collagen-processing and chaperone genes can be performed.

### 156.4.6 Cole–Carpenter Syndrome

This is a rare syndrome characterized by severe bone fragility and metaphyseal and rib fracture often presenting in the first 9 months of life. The radiographic features in the skeleton may be similar to those reported in non-accidental injury. In addition, there is proptosis, craniosynostosis, and prominent vascular markings over the anterior cranium which become more evident in the second 6 months of life. Deformity of the long bones and spine is progressive. The subsequent course is very similar to that seen with progressively deforming OI with marked growth failure. Computerized tomographic 3D reconstruction of the skull confirms craniosynostosis with a number of unusual patterns. One such pattern shows sagittal fusion but parasagittal extension of the anterior fontanelle posteriorly. The mode of inheritance is unknown but presumably results from fresh dominant mutation (99). Type I collagen biochemical screening for mutations has proven negative.

**156.4.6.1 Management.** Cole–Carpenter syndrome should be managed as for OI type III. Neurosurgical intervention may be required for hydrocephalus. Osteoporosis in Cole–Carpenter syndrome appears to be responsive to treatment with cyclic intravenous pamidronate.

### 156.4.7 Osteogenesis Imperfecta with Congenital Joint Contractures (Bruck Syndrome)

Bruck syndrome (BS) was delineated in 1989 by Viljoen et al. (100). It is a recessively inherited disorder characterized by bone fragility and joint contractures, which may be present at birth or develop during childhood and are progressive in nature. In some cases, the major joints of the upper and lower limbs show webbing (pterygia). Wormian bones are present, but the sclerae are white and the teeth are normal.

**156.4.7.1 Molecular Pathology.** Genetic studies indicate that at least two types of Bruck syndrome can be distinguished. One type maps to chromosome 17q and results from mutations in *FKBP10*. In some instances of progressively deforming OI resulting from mutation in *FKBP10*, talipes and congenital joint contractures are

present, but in other patients mutations result in brittle bones alone (86). The second type of Bruck syndrome is not linked to 17q but to mutations in the specific lysyl hydroxylase 2 gene (*PLOD2*) which is located on chromosome 3q23–q24 (11,101). To date, all cases have had congenital joint contractures. Thus there are at least two genes where mutations result in OI syndromes with congenital joint contractures: BS type I resulting from mutations in *FKBP10* and BS type 2 resulting from mutations in *PLOD2*.

**156.4.7.2 Management.** The Bruck syndromes should be managed as for severe OI. Management of the osteoporosis and bone fragility may be necessary before serial splinting can be safely undertaken. The osteoporosis of BS is responsive to treatment with cyclic intravenous pamidronate, although experience is limited.

## 156.5 OTHER MANIFESTATIONS OF OSTEOGENESIS IMPERFECTA

### 156.5.1 Hearing Impairment and Vestibular Function in OI

Hearing impairment is a frequent finding in adults with OI types I, III, and IV and is progressive with age (63,64,102). In a large population study in Finland, almost 58% of patients had audiometrically demonstrable hearing loss. Hearing loss commenced in the second to fourth decades and was initially conductive but progressive such that mixed hearing loss was the most frequent finding in older patients. In most population studies, hearing loss occurs more frequently in OI type I.

Vestibular dysfunction resulting in episodic vertigo was reported in 52% of a Finnish cohort of adult patients (>19 years). Patients with hearing loss had more vertigo (62.5%) than adults without hearing loss.

**156.5.1.1 Management.** Almost 13% of subjects in the Finnish study had hearing loss without recognizing it. Regular audiometry should be performed commencing from adolescence onwards, to diagnose onset of hearing loss and monitor its progress. Rarely, hearing loss due to a combination of factors occurs prior to 12 years so that if hearing loss is suspected in younger patients, audiometry should be performed. Hearing aids should be supplied with satisfactory restoration of hearing. For the majority of patients with bilateral hearing loss, fitting both ears gives a better functional result than fitting one ear. The mixed loss in OI is progressive with age so that in time the benefit may diminish (64). Stapedectomy may restore hearing in young patients with conductive hearing loss. The best outcomes are achieved in centers with special expertise in stapedectomy in subjects with OI. The pathology of hearing loss poses certain surgical difficulties. In OI type I, there may be a thick vascular mucosa with excessive bleeding tendency (103).

**FIGURE 156-7** Severe basilar impression. CT sagittal midline reconstruction of skull base showing odontoid 18mm above Chamberlain's line (tip of hard palate to midpoint and posterior lip of foramen magnum).

### 156.5.2 Craniocervical Anomalies and Basilar Impression

Prior to the era of bisphosphonate therapy, craniocervical anomalies and basilar impression of the skull base occurred in 25% of subjects with OI (71). Basilar impression results from the combination of ligamentous laxity and soft base of skull. It remains to be determined if bisphosphonate therapy decreases the frequency of this complication. Basilar impression is mainly confined to adults with moderate to severe OI type III or IV and is more common in those with dentinogenesis imperfecta. The process of basilar impression, defined as protrusion of the tip of the odontoid process 5 mm above Chamberlain's line or 7 mm above McGregor's line, is associated with characteristic symptoms and signs. The headache is characteristically induced by coughing or sneezing, and radiates to the occiput. Trigeminal neuralgia, vertigo, and weakness in arms and legs may occur. Localizing features on neurologic examination include upbeat or downbeat nystagmus, facial spasm or paresis, and pyramidal signs (104). These signs should be sought in all individuals with OI. Investigation includes lateral base of skull radiographs and serial CT with midline reconstruction.

Subjects with basilar impression on CT (see Figure 156-7), or symptoms and signs, should go on to MRI of the craniocervical junction (see Figure 156-8). Hydromyelia of the upper cervical cord has been reported.

**156.5.2.1 Management.** Occipitocervical fusion does not prevent the progression of basilar impression. The definitive operation is trans-oral or transnasal

**FIGURE 156-8** Severe basilar impression. Midline sagittal MRI T1-weighted image showing upward and posterior displacement of the clivus with angulation and compression at the pontomedullary junction.

anterior clivectomy and decompression of the craniocervical junction (105,106). Reclined seating of babies and young infants with moderate to severe forms of OI and early treatment with cyclic intravenous pamidronate may prevent the development of basilar impression (71).

## 156.6 SYNDROMES WITH OSTEOPOROSIS AND EYE DISEASE

### 156.6.1 Osteoporosis–Pseudoglioma Syndrome

Osteoporosis-pseudoglioma (OPG) syndrome is rare and characterized by generalized osteoporosis leading to fractures and deformity of long bones and spine, and progressive abnormalities of the anterior and middle segments of the eye (107). (Synonym: ocular form of OI.) Histology of bone biopsy specimens demonstrates decreased core width and trabecular bone volume.

The eye findings include microphthalmia, microcornea, corneal opacities, shallow anterior chamber, iris atrophy, and lens opacity. The changes in the eye result from persistence of the hyaloid remnant and are initially characterized as pseudotumors then progress to phthisis bulbar in infancy or childhood (108). Sadly, some patients have had enucleation of the eye as a result of misdiagnosis. Mental retardation, hypotonia, and joint hypermobility and ventricular septal defect are variable manifestations.

When strictly defined, this autosomal recessive syndrome is due to mutations in LDL-receptor-related protein 5 (LRP5) (109). Obligate carriers have a reduced bone mineral density and may have an increased incidence of osteoporotic fractures (109). LRP5 is intrinsic to the WNT signaling pathway and bone formation. The full extent of the clinical and molecular heterogeneity in OPG syndrome is still to be elucidated.

### 156.6.2 Geroderma Osteodysplasticum

This disorder is a mixed connective tissue disorder with features of both OI and Ehlers–Danlos syndrome. Affected children have osteopenia with platyspondylia and multiple Wormian bones in the skull. Fractures occur uncommonly. Eich et al. reported that radiographs of the knees show a metaphyseal peg indenting the distal femoral epiphyses (110). These patients have both hyperelasticity of their skin and hypermobility of joints. The skin is thin and transparent, and on the hands finely wrinkled similar to the appearance in Ehlers–Danlos syndrome type IV and dominantly inherited cutis laxa. Geroderma osteodysplasticum is an autosomal recessive disorder and results from mutations in the *GORAB* gene on chromosome 1q24 (111). A similar but distinct disorder with cutis laxa and progeroid features, including multiple Wormian bones in the skull, results from mutations in *PYCR1* (112).

## 156.7 HYPOPHOSPHATASIA

Hypophosphatasia includes several conditions with overlapping phenotype characterized by bowing deformities of the skeleton of varying severity and a reduced serum alkaline phosphatase due to deficiency of the tissue non-specific alkaline phosphatase (TNSALP). There is also elevation of serum and urinary phosphoethanolamine (113).

Seven clinical phenotypes can be distinguished: perinatal lethal, perinatal benign, infantile, childhood, adult, odontohypophosphatasia, and pseudohypophosphatasia (114). Clinical and radiographic findings in each group show a significant correlation with TNSALP residual activity, site-directed mutagenesis, and computer-assisted modeling studies of TNSALP mutations (115).

### 156.7.1 Perinatal Lethal Hypophosphatasia

Neonates with perinatal lethal hypophosphatasia show disproportionately short limbs with bowing or angulation deformity. The skull vault is thin and membranous. Radiographic studies show extremely poor ossification throughout the skeleton, with thin ribs, hypoplastic vertebrae, demineralized facial bones, and markedly reduced ossification of the skull vault. The metaphyses

of the long bones are frayed and splayed, sometimes with a moth-eaten appearance.

Occasional absence of ossification of one or more vertebral centers or ribs is a characteristic feature. There are usually angulation deformities of the leg and forearm bones. Occasionally ossified “spurs” protrude laterally from ulnae and fibulae.

In the most severe cases death occurs prenatally or in the newborn period, due to respiratory distress associated with seizures and encephalopathy. The serum alkaline phosphatase is low, and the TNSALP measured in cultured fibroblasts is extremely low or undetectable.

### 156.7.2 Perinatal Benign Hypophosphatasia

There are patients who are ascertained perinatally by ultrasound examination who, following birth, appear to have gradual resolution of their skeletal manifestations. Follow-up of these patients suggests that they follow either an infantile or later onset course.

### 156.7.3 Infantile Hypophosphatasia

This form presents before 6 months of age with failure to thrive and signs of rickets, or with pyridoxine-responsive seizures in the first few weeks of life (116). While the cranial sutures are wide, there may be functional craniosynostosis, which progresses if an infant with this form survives infancy. Long-bone deformity and fractures frequently occur. Hypercalcemia and hypercalciuria cause recurrent vomiting, nephrocalcinosis, and renal failure. Spontaneous remission of the bone disease may occur.

Radiologically, there is severe generalized osteopenia with bowing of long bones, lucent defects particularly around growth plates, and fraying of metaphyses. There is frequently a transition from calcified diaphysis to uncalcified metaphyses. Sequential studies show progressive changes of rickets and demineralization.

### 156.7.4 Childhood Hypophosphatasia

Diagnosis is usually made in the second year of life because of an abnormal gait or fractures. There is premature loss of deciduous teeth. Rachitic deformities with enlargement of wrists, knees, and ankles contribute to an abnormal “painful” gait. Radiographically there is metaphyseal fraying with focal bone defects. Functional craniosynostosis occurs and the skull may develop a copper-beaten appearance.

### 156.7.5 Odontohypophosphatasia

In these subjects there is premature loss of deciduous and permanent teeth and biochemical evidence of a raised

level of phosphoethanolamine. Serum alkaline phosphatase (total) may be normal, as a low TNSALP may be masked by other alkaline phosphatase (ALP) isoenzymes, e.g. intestinal ALP.

### 156.7.6 Adult Hypophosphatasia

This usually presents in adult life. There is a frequently a history of premature loss of deciduous teeth and/or rickets. Laboratory findings include raised phosphoethanolamine, and densitometric (DEXA) and radiographic studies confirming osteopenia. Pseudofractures in the lateral cortices of the proximal femora are characteristic of hypophosphatasia.

### 156.7.7 Management

**156.7.7.1 Investigations.** Diagnosis is usually suspected as a result of the clinical presentation and radiographic studies demonstrating metaphyseal fraying, osteopenia, and lucent lesions in the skeleton. Lethal cases may have a moth-eaten appearance. In nonlethal cases, measurements of serum calcium, phosphate, alkaline phosphatase, and urinary phosphoethanolamine may strongly support the diagnosis. An elevated quantitative urinary phosphoethanolamine may be diagnostic. Where biochemical and molecular diagnosis is feasible, a skin biopsy for cultured skin fibroblasts should be collected from affected children. TNSALP activity can be measured in skin fibroblasts and there is then a ready source of DNA for molecular studies. Diagnosis may also be made by direct analysis of the *TNSALP* gene from peripheral blood.

**156.7.7.2 Therapy.** There has been, until recently, no definitive treatment for severe hypophosphatasia (113). However, enzyme replacement therapy with ENB-0040, a bone-targeted recombinant human TNSALP, has been shown to reverse the bone pathology in some severely affected infants (117). Calcitonin, glucocorticoid, calcium restriction, and chlorothiazide may also correct the hypercalcemia and improve bone mineralization in children with perinatal or infantile disease (118). Load-bearing intramedullary rods have proven beneficial in the management of fractures and pseudofractures in adults with hypophosphatasia (114).

**156.7.7.3 Genetics.** In the vast majority of perinatally lethal, infantile, and childhood cases, the disorder is inherited as an autosomal recessive trait. In adult cases, both autosomal dominant and autosomal recessive modes of inheritance have been observed. Apparent autosomal dominant inheritance may result from pseudo-dominance arising from compound heterozygosity for mild mutations (119).

**156.7.7.4 Molecular Genetics.** The alkaline phosphatase in chondro-osseous tissue is important in the hydrolysis of phosphate esters to release phosphate ions for normal calcification. In congenital hypophosphatasia, a

deficiency in the production or stability of bone alkaline phosphatase enzyme leads to a deficiency in the availability of free phosphate necessary for calcification. The tissue alkaline phosphatase gene (*TNSALP*) is located on chromosome 1 close to the Rh locus at 1p36.1–34.

The majority of mutations in patients with perinatal and infantile forms result in significant reduction in levels of TNSALP. These include the majority of nonsense, frameshift, and splicing mutations, and mutations which affect the active site of the TNSALP enzyme predicting a severe phenotype (115,120).

**156.7.7.5 Genetic Counseling and Prenatal Diagnosis.** There is a 25% recurrence risk for hypophosphatasia in sibs. Prenatal diagnosis can be achieved by measurement of the TNSALP in cultured chorionic villus cells. When specific mutations can be found, direct DNA analysis is possible (119).

**156.7.7.6 Differential Diagnosis.** Pseudohypophosphatasia is the term used by Scriver and Cameron (1969) to describe patients with clinical and radiographic findings of hypophosphatasia in the presence of a normal serum alkaline phosphatase, but elevated urinary phosphoethanolamine (121).

## 156.8 OTHER BONE FRAGILITY DISORDERS

### 156.8.1 Chronic Recurrent Multifocal Osteomyelitis and SAPHO Syndrome

Chronic recurrent multifocal osteomyelitis (CRMO) is a disorder characterized by recurrent episodes of painful osteolytic lesions in children, with radiographic appearances suggesting sub-acute or chronic osteomyelitis (122). It is frequently associated with recurrent episodes of pustular lesions on hands and feet. The disorder is multifocal and most often seen in the spine and pelvic bones, and the tubular bones particularly around the knees and clavicles. In the spine, there may be destructive changes with complete disruption of vertebrae, reminiscent of eosinophilic granuloma. Mandibular involvement has also been reported. Spontaneous remission of osteolytic lesions may be observed. These patients often have generalized osteopenia and may present with vertebral crush fractures in adjacent vertebrae (123,124).

The SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, and osteitis) may be a related disorder in adults. In SAPHO syndrome, there is peripheral arthritis, hyperostosis of the anterior chest wall involving sternocostal or sternoclavicular joints, and destructive lesions of the thoracolumbar vertebrae.

**156.8.1.1 Molecular Pathology.** Majeed syndrome comprises chronic recurrent multifocal osteomyelitis and congenital dyserythropoietic anemia with palmar-plantar pustulosis. It is due to mutations in Lipin 2 (*LIPIN2*), localized to chromosome to 18p. The chronic

multifocal osteomyelitis (CMO) mouse, which has autosomal recessive inheritance of a disorder similar to that in man, results from homozygous mutations in the proline-serine-threonine phosphatase-interacting protein 2 gene (*Pstpip2*) (125).

**156.8.1.2 Therapy.** Non-steroidal anti-inflammatory medications alone, or in combination with oral glucocorticoids, are generally effective in this condition (122). However, treatment with cyclic intravenous pamidronate not only corrects the osteopenia in CRMO but may result in healing of the focal destructive lesions in vertebrae, and given the significant correction of bone pathology, may be the treatment of choice at the present time (123). Cyclic intravenous pamidronate has also been used with effect in SAPHO syndrome.

### 156.8.2 Singleton–Merten Syndrome

This syndrome of generalized osteoporosis is characterized by unusual changes in hand bones with expansion of the marrow space. It is further characterized by progressive calcification of the thoracic aorta and calcific aortic stenosis and dental dysplasia. The disorder may result from autosomal dominant inheritance (126). The disorder bears some similarities to idiopathic infantile arterial calcification (IIAC), which has recently been shown to result from homozygous mutations in ecto-nucleotide pyrophosphatase/phosphodiesterase 1E (NPPI) activity (127). Patients with IIAC have spontaneous periarticular as well as aortic calcifications in early life.

### 156.8.3 Neonatal Hyperparathyroidism

Infants with neonatal hyperparathyroidism generally present with a narrow chest, simulating thoracic dysplasia (128). Leg bowing is often present. Chest radiographs show rib fractures and severe osteopenia, but long bones show periosteal cloaking with periosteal calcification and subperiosteal lucency. The mandible is osteopenic and the metaphyses irregular. The radiographic findings must be distinguished from OI type II where the femora are crumpled (accordion-like), and perinatally lethal infantile cortical hyperostosis (Caffey disease) where the mandible and clavicles are hyperostotic. Neonatal hyperparathyroidism is usually a self-limited disorder with spontaneous regression over the first four months of life.

Mucopolipidosis II (MLII) is a group of disorders resulting in defective lysosomal phosphotransferase, which may disturb signal transduction through the calcium-sensing receptor. The perinatal hyperparathyroidism commonly seen in MLII is similarly self-limited and remits in the first 4–6 months, although dysostosis multiplex is progressive. After the first year, patients with MLII manifest radiographic and histopathologic features

characteristic of hyperparathyroidism but with normal serum parathyroid hormone, which has been designated pseudohyperparathyroidism (129).

**156.8.3.1 Management.** Neonatal hyperparathyroidism is usually a self-limiting disorder. Severely affected infants may die as a result of thoracic insufficiency. Hypercalcemia should be managed conservatively.

### 156.8.4 Infantile Cortical Hyperostosis (Caffey Disease)

Infantile cortical hyperostosis (ICH) presents in fetal or early infantile life with clinical evidence of a systemic bone disorder (96). Prenatal onset may result in limb bowing and irregularity of ribs, simulating multiple rib fractures (130). Radiographs show massive subperiosteal new bone in ribs, long bones, and mandible. The affected areas are typically inflamed with fever and hot tender swelling.

**156.8.4.1 Genetics.** Autosomal dominant and autosomal recessive inheritance and a sporadic form have been postulated based on clinical and pedigree information. In the dominantly inherited form, the disorder is self-limiting. A postulated autosomal recessive form is usually perinatally lethal. The sporadic “epidemic” form is now rare.

**156.8.4.2 Molecular Pathogenesis.** In three unrelated families with autosomal dominant Caffey disease (ADCD) a heterozygous 3040C>T transition was detected in exon 41 of *COL1A1*, resulting in a R836C mutation in the triple helical domain of pro $\alpha$ (1) chains of type I collagen. Penetrance was not complete, such that 20% of heterozygous carriers of the disease-causing mutation had not manifested Caffey disease. The pathogenesis of ADCD is not completely explained by the *COL1* mutation.

**156.8.4.3 Management.** Corticosteroids and indomethacin have been employed with resolution of symptoms in the sporadic and autosomal dominant forms of ICH. In the forms with fetal onset, there is a high frequency of fetal hydrops and survival is rare although not unknown with supportive therapy (130).

### Biographies

**Prof. David Sillence**, MBBS, MD (Melb), FRACP, FRCPA, FAFPHM, FAFRM, FFSc(RCPA) is a professor of Medical Genetics in the Sydney Medical School and a consultant physician to the Connective Tissue Dysplasia Clinic and Centre for Children's Bone Health in the Sydney Children's Hospital Network (Westmead) since 1980. He trained both at the Murdoch Institute with David Danks and at the Cedars–UCLA International Skeletal Dysplasia Registry with David Rimoin. He has worked in the field of genetic disorders of bone and mineral metabolism for four decades. Since 1980, with colleagues from Westmead, Professor Sillence has developed a comprehensive multidisciplinary program for the skeletal investigation and medical treatment of children with connective tissue dysplasias encompassing genetic skeletal dysplasias, genetic bone and mineral disorders, Ehlers–Danlos syndromes, and related disorders.

Prof. Sillence and his collaborators pioneered the evaluation of bone density by dual-energy X-ray absorptiometry in children, and treatment of osteoporosis with various regimens of the class of drugs known as bisphosphonates, in Australia. He has been a member of the International Nomenclature Committee for Constitutional Disorders of the Skeleton since 1986. With Dr Jenny Ault he commenced the Osteogenesis Imperfecta Clinic in 1987 as part of the larger Connective Tissue Dysplasia Service in the Sydney Children's Hospital Network (Westmead Campus).

**Assoc. Prof. Craig Munns**, MBBS, PhD, FRACP is a Senior Staff Specialist in Bone and Mineral Medicine at the Children's Hospital at Westmead. He completed his pediatric and endocrinology training at The Royal Children's Hospital, Brisbane, Australia, and was then appointed as Clinical Associate in Genetic and Metabolic Bone Disorders at the Shriners Hospital for Children, Montreal, Canada, under Dr Francis Glorieux and Dr Frank Rauch.

Assoc. Prof. Munns obtained his PhD through the University of Queensland. He has expert knowledge in the diagnosis and management of pediatric bone disorders. At The Children's Hospital at Westmead, Associate Professor Munns has established collaborative links with many groups throughout the hospital and is uniquely placed to investigate and manage the care of children with bone disorders. He has also established a strong relationship with basic bone scientists at the hospital. He has established collaborative links throughout the hospital and introduced pQCT, bone biopsy for histomorphometry, functional muscle assessment, additional bone turnover markers, and vibration platforms into the hospital.

Assoc. Prof. Munns' major research interests are in novel therapeutic approaches to children with primary and secondary bone disorders and he has published in this area.

This article is a revision of the previous edition article by David O Silence, Graig F J Munns, volume 3, pp 3692–3708, © 2007, Elsevier Ltd.

### 157.1 INTRODUCTION

More than 30 disorders are known with generalized or localized increase in the density or size of the skeleton or individual skeletal elements.

### 157.2 OSTEOPETROSIS GROUP OF DISORDERS

Osteopetrosis has traditionally been subdivided on the basis of the age at presentation. However, the situation is considerably more complex, and an increasing number of genetically distinct disorders have been described with an overlapping spectrum of clinical and radiographic features. The systematic study of spontaneously occurring and transgenic mouse mutants has predicted more than 18 genetic defects that might result in osteopetrosis (1). These studies provide a broad grouping of osteoclast defects into:

- (1) Defects of early osteoclast differentiation
- (2) Defects in receptor activator of nuclear factor  $\kappa$ B (NF- $\kappa$ B) and related proteins
- (3) Defects in osteoclast function
- (4) Defects in acidification by the osteoclast.

#### 157.2.1 Defects in Early Osteoclast Differentiation

In the mouse, osteoclast differentiation depends on M-CSF (mouse-colony stimulating factor) and its receptor, the transcription factor PU.1, and the microphthalmia basic helix-loop-helix zipper transcription factor (Mitf). Mutations in each of these genes results in a type of murine osteopetrosis.

#### 157.2.2 Defects in Receptor Activation of Nuclear Factor $\kappa$ B and Related Proteins

Osteoclast differentiation is also dependent on the interaction of osteoprotegerin with RANKL (receptor activator of nuclear factor  $\kappa$ B ligand). The interaction between RANKL and RANK is a major determinant of bone mass. RANK signaling is influenced directly by c-fos, NF- $\kappa$ B, and TRAF-6 (tumor necrosis factor receptor-associated factor 6). Murine osteopetrosis has been observed in murine knockout of RANK, RANKL, c-fos, NF- $\kappa$ B subunits, and TRAF-6.

#### 157.2.3 Defects in Osteoclast Function

A large number of proteins are important for osteoclast function, including tyrosine kinase c-src, osteopetrosis-associated transmembrane protein (OSTM1; the protein product of the *Gl* gene), the enzyme cathepsin K, and tartrate-resistant acid phosphatase (TRAP), which has a role in intracellular transport. Mutations in their genes also result in murine osteopetrosis. Anchoring of osteoclasts in bone is important, as demonstrated by the observation of osteopetrosis in mice with mutations in  $\alpha$ V $\beta$ 3 integrin.

#### 157.2.4 Defects in Acidification

This group of disorders has been the most productive for the delineation of mouse–human homology. Mice mutant for defects in the ATP-dependent osteoclast-specific vacuolar proton pump (ATP6i or TCIRG1) and mice with mutations in the CLCN7 chloride channel gene develop a form of osteopetrosis. Human carbonic anhydrase II deficiency results in renal tubular

acidosis and infantile onset of osteopetrosis, fractures, and developmental delay.

The observation that mammalian osteopetrosis can be cured by parabiosis has led to successful cures with bone marrow transplantation in laboratory animals and in the human disorder (2). Knowledge from animal models should hopefully guide treatment in human disorders in the future. The full spectrum of osteopetrosis in humans will have to await the molecular characterization and genotype/phenotype correlation in these rare disorders, but at present the clinical grouping includes:

- (1) Osteopetrosis with precocious manifestations (several forms, including autosomal recessive osteopetrosis (ARO), severe neonatal, and malignant forms)
- (2) Osteopetrosis with usually delayed onset (several forms, including Albers–Schonberg; autosomal dominant osteopetrosis type II (ADOII or osteopetrosis late onset); and osteopetrosis, intermediate type (IAO))
- (3) Osteopetrosis with autosomal recessive inheritance (mild type)
- (4) Osteopetrosis with renal tubular acidosis.

### 157.2.5 Osteopetrosis with Precocious Manifestations

The precocious form of the disease is most frequently discovered during the first few months of life but may present as failure to thrive, malignant hypocalcemia, or anemia with thrombocytopenia (leukoerythroblastic anemia), or even because of severe, perhaps overwhelming infection. Rarely, fractures lead to medical attention (Synonyms: osteopetrosis congenita).

**157.2.5.1 Clinical Findings.** Generalized hyperostosis may be recognized at birth, but usually develops rapidly after birth and leads to crowding of the marrow cavity resulting in anemia and extramedullary hemopoiesis, hepatosplenomegaly, and thrombocytopenia, leading to purpura and ecchymosis. Anemia results from excessive hemolysis. A defect in macrophage killing of bacteria may account for a tendency to severe and overwhelming infection. Progressive encroachment on the optic foramina may lead to optic atrophy and blindness. In some cases, evidence of optic nerve encroachment is present at birth. Hypocalcemia is not an uncommon finding, and serum phosphorus may also be low. Elevated serum alkaline phosphatase is a constant finding. Radiologically, the diagnostic findings are a generalized increase in bone density combined with defective metaphyseal modeling and a “bone-in-bone” appearance, most marked in the vertebral bodies. Diffuse hyperostosis leads to loss of demarcation of the cortex and medullary cavities. Irregular deposition of bone at the metaphyses may produce the appearance of parallel plates of dense bone at the ends of long bones. The skull shows a dense base with normal-to-increased density of the vault and markedly increased density in the orbital margins.

**157.2.5.2 Genetics.** Inheritance is generally autosomal recessive, although some cases with newborn presentation are due to heterozygous mutations resulting in autosomal dominant inheritance or fresh dominant mutation.

**157.2.5.3 Molecular Pathology.** Following the discovery of the murine defect in the osteoclast-specific vacuolar proton pump ATP6i subunit, also known as TCIRG1, on chromosome 11q12, mutations were discovered in 50%–60% of children with severe osteopetrosis (3–5). In Costa Rica, where there is a 10 times expected frequency of osteopetrosis, two missense mutations account for all the known mutations (3). In bone, osteoclasts are present and normal in appearance, and the resorptive defect results from the resulting acidification defect. Aker et al. showed SNX10 to interact with ATP6i (V-ATPase). They found homozygous mutations in the SNX10 gene in eight molecularly negative patients with infantile malignant osteopetrosis (6).

In a further 15% of cases in the same series, mutations were detected in the *CLCN7* gene on chromosome 16p12, which codes for a chloride channel also important in acidification. Although the majority of the patients were homozygous/doubly heterozygous for *CLCN7* mutations, a few patients were heterozygous with only one mutant allele. These presumably represent dominant negative mutations, as the chloride channel protein exists as a multimer and a defect in only 50% of the secreted proteins would disrupt assembly and function of the channel. Homozygous mutations in the human *GL* gene, encoding osteopetrosis-associated transmembrane protein (OSTM1), on chromosome 6q21 (homologous to mouse *gl/gl*) have been reported in 2% of individuals with autosomal recessive osteopetrosis (7,8). OSTM1 protein and *CLCN7* protein colocalize in late endosomes and lysosomes of various tissues forming a molecular complex (8). The *gl/gl* mutant phenotype in the mouse results in a very severe osteopetrosis phenotype with prenatal or perinatal death, so this mutation should be looked for in babies with perinatally lethal osteopetrosis. Mutations such as that in the mouse colony stimulating factor 1 (*MCSF1*) gene, responsible for the *op/op* mouse phenotype (9), or mutations in *PU.1*, have not yet been discovered in human osteopetrosis.

Mutations in the *TNFSF11* gene (*RANKL*) on chromosome 13q14.11 result in a mild form of autosomal recessive osteopetrosis that clinically resembles the autosomal dominant form with a mild T-cell defect (10). Mutations in *TNFRSF11A* (*RANK*) on chromosome 18q21.44 result in osteopetrosis with hypogammaglobulinemia (11).

#### 157.2.5.4 Differential Diagnosis.

(1) **Perinatally lethal osteopetrosis.** Siblings with severe osteopetrosis with in utero fractures were described with hyperdensity and skeletal lesions on ultrasound at 18 weeks' gestation (12). The parents were first cousins. Brain histopathology showed gliosis and axonal swelling with heterotopic islets of immature cells and occasional foci of calcification.

- (2) **Ectodermal dysplasia, anhidrotic with immunodeficiency, osteopetrosis, and lymphedema** (OL-EDA-ID, or X-linked osteopetrosis lymphedema, anhidrotic ectodermal dysplasia, and immunodeficiency). The report of a hemizygous male patient with nonsense-to-sense (TER420TRP) mutation in the NF- $\kappa$ B essential modulator (IKBKG) gene on chromosome Xq28 is the first report of a mutation in this X-linked gene resulting in osteopetrosis. The phenotype is predicted given the importance of NF- $\kappa$ B in RANK signaling and osteoclast proliferation. This is not surprising since osteoclasts and cells of the hematopoietic system have a common origin (13). Heterozygous mutations in *IKBKG* (NEMO) result in incontinentia pigmenti type II in female patients. Mutations in *CalDAG-GEF1* and *Kindlin-3* have been identified in autosomal recessive osteopetrosis variants with leukocyte adhesion deficiency (14,15).
- (3) **Raine dysplasia**. Newborns with Raine dysplasia have diffuse osteosclerosis, wide fontanelles, and a distinctive face.
- (4) **Blomstrand dysplasia**. This perinatally lethal osteosclerosis disorder is characterized by advanced skeletal maturation. It is diagnosable prenatally with features of a short limb skeletal dysplasia and rib and long-bone features, which may be misinterpreted as perinatally lethal osteogenesis imperfecta. It results from autosomal recessive inheritance of inactivating mutations in the parathyroid hormone/parathyroid-hormone-related peptide (PTH/PTHrP) receptor localized to chromosome 3p21–p22 (16).

**157.2.5.5 Management.** *Therapy:* Treatment is aimed at decreasing or arresting progressive hyperostosis and correcting anemia and thrombocytopenia. General supportive measures including prompt and vigorous treatment of infections and minimizing neurologic complications, particularly progressive optic atrophy due to encroachment of the optic foramina. Care should be taken in restricting calcium intake in the subgroup of children who have changes of rickets at the ends of their long bones, so called osteopetro-rickets. Prednisone may ameliorate the progress of the anemia and thrombocytopenia. However, this regimen is rarely helpful in malignant osteopetrosis. Neurosurgical unroofing of the optic foramina has been helpful in some patients, with improved vision postoperatively. In other patients, vision is preserved. Optic atrophy is usually established by the time the disorder is diagnosed. At best, surgical intervention can only ameliorate the visual disability and prevent its progression. Bone marrow transplantation of appropriately human leukocyte antigen (HLA)-matched donor marrow has been curative in some patients (17). The experimental animal data indicates that most types of osteopetrosis, but not all, will be responsive depending on the underlying defect (1). The present data show a 50% survival at a median of 15 months post-transplant.

Families need to be aware that vision is rarely restored following the transplant. Generally, without successful bone marrow engraftment the prognosis for survival is poor, and death from complications such as anemia, bleeding, or overwhelming infection is not uncommon in the first few months or years.

*Genetic counseling and prenatal diagnosis:* For normal parents with one or more infants with congenital osteopetrosis, the risk approximates 25% for a subsequently affected infant. Radiographic prenatal diagnosis has been generally unsuccessful in detecting increased bone density during the second trimester. Direct molecular genetic diagnosis requires the characterization of the molecular defects in the various types of osteopetrosis with precocious manifestations.

### 157.2.6 Osteopetrosis with Later Onset and Juvenile Types

Apart from cases with congenital or infantile presentation of osteopetrosis, there is a group of patients in whom the onset of the disease is recognized later (osteopetrosis tarda or Albers-Schonberg disease). The prevalence was 1 per 18,000 in Denmark (18).

**157.2.6.1 Natural History.** Patients may present in childhood, adolescence, or young adult life because of fracture (greater than 75%), mild craniofacial disproportion, mild anemia, complications arising from neurologic involvement, or osteitis with osteonecrosis, usually of the mandible (19) (Figure 157-1). Encroachment on optic nerves results in visual disability in approximately 5% of patients, but hearing impairment resulting from petrous bone sclerosis occurs in some 25% of individuals with late onset. Increased bone density may be discovered incidentally on routine radiologic study for some non-skeletal problem. Biochemically, there is normal serum calcium, parathyroid hormone (PTH), and calcitonin. Serum acid and alkaline phosphatases may be elevated, the latter with healing fractures.

Skeletal radiographs show generalized increased density of cortical bone with defective metaphyseal modeling of the long bones, resulting in a club-shaped appearance. There is longitudinal and transverse osteodense striation at the ends of the long bones in more than half the patients. The vertebral column shows osteodense vertebral endplates. The base of the skull is usually dense and thickened, but the face and vault are generally less severely involved. There is considerable clinical variability even within the same family. Some affected individuals have been reported that do not exhibit radiographic findings (20). Increased levels in serum of BB-isoenzyme of creatine kinase (CK) and TRAP help in making the diagnosis of autosomal dominant osteopetrosis (21).

**157.2.6.2 Genetics.** In most cases, this milder presentation of osteopetrosis is inherited as an autosomal dominant trait, although families with autosomal recessive inheritance have been reported. Heterogeneity has been

**FIGURE 157-1** Osteopetrosis (later-onset type). Eight-year-old boy with frontal bossing and recurrent fractures.

suggested on phenotypic grounds (22). Several subtypes were proposed but the disorder designated type I is synonymous with endosteal hyperostosis of the Worth type, and due to gain-of-function mutations in *LRP5* (low-density lipoprotein-related protein 5).

**157.2.6.3 Molecular Pathology.** Osteopetrosis of later onset primarily results from heterozygous missense mutations in the *CLCN7* chloride channel gene on chromosome 16p13 (23). Several mutations representing single exon deletions have been reported. Autosomal dominant (AD) osteopetrosis is allelic with severe autosomal recessive (AR) osteopetrosis due to *CLCN7* mutations. Intermediate forms of juvenile osteopetrosis with AR inheritance have been reported also to show homozygosity for missense mutations in the *CLCN7* gene in 40%–60% of intermediate forms of osteopetrosis phenotype (5). Mutations in *CLCN7* have been found in approximately 75% of AD osteopetrosis type II (5).

**157.2.6.4 Management.** Therapy should be directed at recognition and treatment of complications. Bone fragility is a leading complication. Children with osteopetrosis should be educated to avoid body-contact sport and other situations which have a high probability of fracture. These children are likely to have unusual fractures, such as of the femoral neck and hangman fracture of the cervical spine. Transfusion may be required for anemia, and splenectomy may be necessary or useful in some patients with refractive anemia. Splenectomized

patients, however, require antibiotic prophylaxis against encapsulated organisms as they are in double jeopardy first from the disorder and second from splenectomy. Regular, usually annual, testing of visual fields and acuity and baseline radiographs of optic foramina should be carried out during childhood. Regular audiometry should also be performed once the children can be tested by free field audiometry. On the whole, treatment with low-calcium diet, PTH, calcium chelating agents, calcitriol, corticosteroids, and heparin has not shown clear therapeutic advantages.

### 157.2.7 Osteopetrosis with Renal Tubular Acidosis

Osteopetrosis with renal tubular acidosis is an autosomal recessive type of infantile osteopetrosis that presents with fractures and/or short stature, visual impairment, and mental retardation in the first few years of life. (Synonyms: Guibad–Vainsel syndrome, carbonic anhydrase II deficiency, marble brain disease.)

**157.2.7.1 Clinical Findings.** These children present with an intermediate form of osteopetrosis with symptoms of visual disability, mental retardation (some have normal intelligence), and fractures resulting from osteosclerosis. Short stature increases with age. Radiology reveals intracranial ossification, generalized osteosclerosis, and narrowing of the optic foramina. Hematologic investigation demonstrates anemia and evidence of extramedullary hemopoiesis. Serum electrolytes are consistent with a mixed proximal and distal renal tubular acidosis.

**157.2.7.2 Genetics.** This is an autosomal recessive disorder with relatively high gene frequency in Middle Eastern families. More than half the known cases have been in families from Kuwait, Saudi Arabia, and north Africa. Consanguinity was present in 75% of the families reported by Hu et al. in 1992 (24). Prenatal diagnosis may be possible in families with a defined mutation (25).

**157.2.7.3 Biochemistry and Molecular Genetics.** The biochemical defect is in carbonic anhydrase II, an enzyme whose integrity is important for acidification by osteoclasts in the process of mineral resorption and in the renal tubules. Patients generally show a mixed (proximal and distal) renal tubular acidosis. Several different mutations have been described in the carbonic anhydrase II gene, which is localized to chromosome 8q22 (24). The predominant mutation in patients from the Middle East and Africa is a novel splice junction mutation at the 5' end of intron 2 of the carbonic anhydrase II gene, known as the Arabic mutation. In an Italian boy with a splice donor mutation of exon 6, the disorder was unusually mild and the renal tubular acidosis had only a distal component (25).

**157.2.7.4 Therapy.** Management is as for children with moderately severe osteoporosis. Regular monitoring of visual fields, review for cranial nerve encroachment, and developmental/psychometric testing are

important. Vitamin D supplementation is important if rickets develop. Hypokalemia should be corrected with oral potassium. Correction of renal tubular acidosis with oral bicarbonate may aggravate the bone disease.

### 157.3 RAINE DYSPLASIA

Raine syndrome is an autosomal recessive disorder that combines diffuse osteosclerosis with distinctive facial dysmorphism and intracranial calcification (26,27). The dysmorphism includes puffiness of periorbital tissues (Figure 157-2), microcephaly with herniation through anterior or posterior fontanelles, gum hypertrophy, prominent tongue, cleft palate, and low-set ears. Radiographs show osteosclerosis of the facial bones and cranial vault and subperiosteal thickening of ribs, clavicles, and diaphyses of the long bones. Brain ultrasound or magnetic resonance imaging (MRI) reveals calcification unevenly distributed throughout the brain but mainly in periventricular white matter in parietal and occipital lobes. Detailed neuropathology demonstrates single and clumped calciospherites mainly in neuropil but also in perivascular tissues (27). The disorder was thought to be perinatally lethal but an attenuated phenotype has been reported (28).

#### 157.3.1 Genetics

Since the first case was described in 1989, approximately 24 cases have been reported. Consanguinity has

**FIGURE 157-2** Raine syndrome. Newborn showing characteristic puffiness of periorbital tissues and proptosis with short nose and tented upper lip.

been observed and sex distribution has been normal, suggesting autosomal recessive inheritance. There has been a predominance of cases from Middle Eastern families. Mutations in *FAM20C* on chromosome 7p22 have been identified in 11 affected patients (29). *FAM20C* codes for DMP4, a dentin matrix protein that probably plays a role in mineralization (30). Osteopetrosis with renal tubular acidosis appears to be a distinct entity. There is phenotypic overlap between Raine syndrome and desmosterolosis; however, these appear to be distinct entities as intracranial calcification is not observed in desmosterolosis and measurement of the hepatic desmosterol/cholesterol ratio was normal in one case of Raine syndrome (27).

### 157.4 PYKNODYSTOSIS

Pyknodysostosis is a rare generalized hyperostotic bone disease recognized from infancy by short limbs, short stature, characteristic facies, and wide anterior fontanelle persistent into adult life (31). (Synonyms: osteopetrosis acro-osteolytica, pycnodysostosis.)

#### 157.4.1 Clinical Findings

The skull, which appears large with frontal and occipital bossing and a wide anterior fontanelle, may bring the patient to attention. The hands and feet are short and broad, and the nails may be deformed and brittle. The sclerae are often bluish, and this, in combination with a tendency to fractures with minimal trauma, may lead to confusion with osteogenesis imperfecta.

Radiographically, increased bone density is recognizable by 3 years of age. There is a generalized increase in bone density without long-bone or metaphyseal striation. In older patients, the hands characteristically show progressive osteolysis of the distal phalanges, which appear small and fragmented. The characteristic findings in the skull are wide sutures and Wormian bones, and in the face, a small mandible with an obtuse mandibular angle.

#### 157.4.2 Genetics

This disorder is inherited as an autosomal recessive trait. An increased frequency of parental consanguinity has been described in several populations.

#### 157.4.3 Molecular Pathology

Homozygosity by descent was used to map pyknodysostosis to 1q21 (32). Gelb et al. then demonstrated that mutations in the cathepsin K gene were responsible for pyknodysostosis. Nonsense, missense, and stop codon mutations have all been reported. Cathepsin K is a lysosomal protein responsible for proteolytic degradation

in the osteoclast. Homozygosity for ala277val resulting from paternal uniparental isodisomy for chromosome 1 has been reported (33). In mice, cathepsin K transcription is regulated by a number of transcription factors in *Mitf*.

#### 157.4.4 Genetic Counseling

For normal parents, there is a 25% risk for further affected offspring. Ultrasound prenatal diagnosis is not feasible. If a mutation in the cathepsin K gene can be demonstrated, direct DNA diagnosis in chorionic villus could be performed.

### 157.5 DYSOSTEOSCLEROSIS

Dysosteosclerosis is a rare autosomal recessive skeletal dysplasia characterized by generalized increase in bone density and short stature of postnatal onset. It is differentiated from osteopetrosis and pyknodysostosis by radiologic evidence of platyspondylia with superior and inferior irregularity of vertebral ossification, and clinical findings of a high incidence of development defects of the teeth with delayed eruption of primary dentition, severe hypodontia, and early loss of the teeth (34). Secondary dentition may fail to erupt. Otherwise, the complications consisting of fractures, visual and hearing loss, and recurrent infections of mandible and paranasal sinuses are very similar to those encountered in osteopetrosis. The etiology of this disorder remains unknown.

### 157.6 OSTEOPOIKILOSIS, BUSCHKE–OLLENDORF SYNDROME, AND MELORHEOSTOSIS

Osteopoikilosis and melorheostosis are most commonly asymptomatic and are usually recognized during routine radiologic study including skeletal films. Occasionally, patients are seen with both types of lesions.

#### 157.6.1 Osteopoikilosis

In osteopoikilosis, many small, round or oval osteodense foci are seen in the skeleton, most commonly in the epiphyses and carpal and tarsal centers. The lesions represent foci of old remodeled bone with lamellar structure (35). The disorder is associated with joint pain in some 20% of cases and with skin lesions in an unknown proportion. Osteopoikilosis can occur in isolation or in association with connective tissue nevi of the skin, a condition termed Buschke–Ollendorf syndrome. These consist of slightly elevated whitish-yellow fibrocollagenous nevi (dermatofibrosis lenticularis disseminata) or elastic-type nevi (juvenile elastoma). There is an increased incidence of keloid formation.

#### 157.6.2 Melorheostosis

In melorheostosis, irregular linear osteodense lesions are seen along the axis of the tubular bones. The radiologic appearance of the osteodense lesions has been likened to candle wax flowing down the side of a candle. Single or multiple areas of the skeleton may be involved. The pattern of lesions may be correlated with the sensory scleromeres. It has been suggested that melorheostosis may be the late consequence of lesions of the sensory nerve supply to various skeletal elements (36). The lesions may be associated with shortening of certain bones leading to discrepancy in limb length, soft tissue contractures of the joints or palmar and plantar fasciae, and intermittently painful swelling of affected joints, muscle atrophy, hemangiomas, or lymphedema.

#### 157.6.3 Genetics of Osteopoikilosis and Melorheostosis

Osteopoikilosis can occur either as an isolated anomaly or as part of the Buschke–Ollendorf syndrome, which is inherited as an autosomal dominant disorder with variable expressivity (see above). Melorheostosis usually occurs sporadically but may occur in families inheriting osteopoikilosis and dermatofibrosis lenticularis.

#### 157.6.4 Molecular Genetics

The LEM-domain-containing 3 gene (*LEMD3*) on chromosome 12q13 functions to regulate BMP and transforming growth factor beta (TGFβ) signaling in bone and connective tissue by antagonizing both signaling pathways (35). Loss-of-function mutations have been demonstrated in three families with osteopoikilosis who simultaneously also segregated Buschke–Ollendorf syndrome (35).

#### 157.6.5 Management

Management is directed at the connective tissue, skin, and orthopedic complications.

### 157.7 OSTEOPATHIA STRIATA

In osteopathia striata, which also may demonstrate autosomal dominant inheritance, linear regular bands of increased density are seen throughout the skeleton, radiating vertically from metaphyses and with fan-like array in the iliac wings. These should be distinguished from similar striations seen in osteopetrosis, which are associated with metaphyseal modeling defects, and transverse bands of osteodensity at the ends of the long bones. Typical changes of osteopathia striata are seen in diverse syndromes.

In the syndrome of focal dermal hypoplasia (Goltz syndrome), lesions consisting of dermal hypoplasia with

herniation of the adipose tissue are combined with skeletal defects of the limbs (hypoplasia, aplasia, and syndactyly) are inherited in an X-linked dominant fashion. In SPONASTRIME dysplasia (**spondylar-nasal-striated-metaphyses**), the osteopathia striata is not evident until late childhood. This is an autosomal recessive spondylo-metaphyseal dysplasia with severe short stature.

### 157.7.1 Osteopathia Striata with Cranial Sclerosis

Osteopathia striata may also be inherited along with cranial sclerosis (OSCS) as an X-linked dominant syndrome (37). In this syndrome there is associated psychomotor retardation (17%), hearing deficiency (80%), and congenital heart defects. Macrocephaly is seen with frontal bossing in virtually all patients and radiographic study shows cranial hyperostosis. The appendicular skeleton can also be involved. Although there is a high frequency of deafness, the progressive encroachment on cranial foramina is not as marked as in other craniotubular remodeling disorders (see Section 157.8). Nevertheless, facial palsy and palsy of other cranial nerves has been reported. Spontaneous remission of some cranial nerve palsies occurs.

### 157.7.2 Genetics

There is an excess of affected females, and female patients are more likely to have more severe disease-related complications. Mutations in the *WTX* gene on chromosome Xq11.1 causes OSCS. *WTX* is a tumor-suppressor inhibitor of canonical WNT signaling (38). *WTX* protein contains an acidic domain (AD), a  $\beta$ -catenin binding site, and three binding sites for adenomatous polyposis (ADC). Jenkins et al. attributed the cellular mechanism underlying the hyperostotic phenotype to osteoblast activation, inhibition to osteoclast differentiation, or redirection of pluripotent stem cell differentiation. Nonrandom X-inactivation has been demonstrated in an affected female with a severely affected son (39).

## 157.8 CRANIOTUBULAR REMODELING DISORDERS

Craniotubular remodeling disorders are a large group of hyperostoses characterized by abnormal modeling as well as increased density of bone. A distinction has been drawn between the craniotubular dysplasias (e.g. craniodiaphyseal dysplasia), in which modeling abnormalities are prominent (40) although there is also severe sclerosis of the skull, and the craniotubular hyperostoses (e.g. endosteal hyperostosis (van Buchem's syndrome)), in which cranial and tubular bones are deformed by overgrowth of osseous tissue, rather than by a defect in bone remodeling. This distinction is somewhat arbitrary, as all these disorders result from excess bone deposition

versus resorption with specifically different patterns of skeletal involvement. In essence, they are all disorders in which there is generally minimum involvement of the spine compared with osteopetrosis, pyknodysostosis, and dysosteosclerosis, in which increased osteodensity is seen throughout the spine and the rest of the skeleton with minimal changes in the cranial vault.

In diaphyseal dysplasia (Camurati-Englemann disease; CED), craniodiaphyseal dysplasia, the craniometaphyseal dysplasias, frontometaphyseal dysplasia, and pachydermoperiostosis, sclerosis in the region of optic foramina may lead to visual impairment, papilledema, and optic atrophy. Sclerotic narrowing of internal acoustic foramina and the middle ear may lead to various patterns of conductive or sensorineural hearing loss; encroachment on the facial foramina may lead to facial paresis and encroachment on the foramen magnum to long tract signs, hyper-reflexia, weakness, and even sudden death or paraplegia.

### 157.8.1 Diaphyseal Dysplasia (Camurati-Englemann Disease)

Diaphyseal dysplasia is a rare craniotubular remodeling disorder (also known as progressive hereditary diaphyseal dysplasia) with significant neuromuscular involvement (41).

**157.8.1.1 Clinical Findings.** Symptoms usually begin between 4 and 10 years of age, but the onset of symptoms has been described as early as 3 months and as late as the sixth decade. Failure to thrive or gain weight, fatigability, and abnormal gait are frequent presenting symptoms. Pain in the legs of progressively increasing severity may occur. The gait is characteristically wide based and waddling, with reduced muscle mass and poor muscle tone. Flexion contractures may develop at the elbows and knees. Bowleg or knock-knee deformity may be seen in the lower limbs, and the feet may be flat and pronated. Deep tendon reflexes in some cases have been hypoactive and in others hyperactive, with occasional ankle clonus. Increased lumbar lordosis and scoliosis may occur with variable degrees of back pain. Symptoms and signs of encroachment on cranial nerves may be present.

The radiographic features include symmetrical fusiform enlargement of the diaphyses of the long bones, with normal epiphyses and metaphyses. In the diaphyses, there is enlargement of the cortex by endosteal and periosteal accretion of mottled new bone. The lesions are often first recognized centrally in the long bones and progress proximally and distally with gradual involvement of adjacent normal bone. In the skull, there may be sclerosis of the base and frontal areas.

Serum calcium, phosphorus, and serum alkaline phosphatase are characteristically normal. Muscle histology has been reported to show loss of individual muscle fibers with replacement by adipose tissue, atrophic muscle fibers, and slightly pyknotic sarcolemmal

cell nuclei with hyalinization and decrease in the prominence of cross-striations. There is an increased frequency of autoimmune complications, which includes vasculitic pathology, anemia, neutropenia, and thrombocytopenia in some patients. The response to steroid therapy further suggests an immune contribution to the pathogenesis (42).

**157.8.1.2 Genetics.** Camurati–Engelmann dysplasia is inherited as an autosomal dominant trait with variable penetrance and wide expressivity. There is considerable variation in the signs, symptoms, and severity between affected individuals within the same family.

**157.8.1.3 Molecular Genetics.** *TGFβ1* has been shown to stimulate bone formation and suppress bone resorption under physiological conditions (43). A cluster of mutations in *TGFβ1* in the region of the carboxyl terminus of the latency-associated peptide (LAP) domain has been delineated (44,45). The multiple tissue regulatory functions of *TGFβ* may explain the wide variety of extra-skeletal manifestations observed in patients with CED, including the muscle weakness. The pathogenesis of CED is yet to be completely elucidated. *TGFβ1* on chromosome 19q13.2 is the only gene known to be associated with CED. Mutations which inhibit secretion of *TGFβ1* caused upregulation of the signaling pathway (46). The majority of mutations are sense-to-missense in the signaling and LAP domain, resulting in intracellular retention of mutant nascent peptide with decreased secretion.

#### 157.8.1.4 Differential Diagnosis.

- (1) **Camurati–Engelman disease type II.** Nishimura and colleagues reported two patients with clinical features of progressive diaphyseal dysplasia but striations of bones. The disorder appeared to be clinically distinct from hyperostosis generalisata with striations of the bones and mutations that were not detected in the LAP protein region of *TGFB1* (47).
- (2) **Hyperostosis generalisata with striations of the bones (HGS).** This appears to be a disorder distinct from osteopathia striata with cranial sclerosis. It is characterized by cortical thickening of tubular bones and thick bony trabeculae of tubular bones, spine, and skull (48).

**157.8.1.5 Management.** Therapy for this condition should be aimed at maximizing the mobility of the patient. Orthopedic correction of deformity of lower limbs by appropriate osteotomy has been reported to help in the habilitation of these patients. There have been reports of good symptomatic response to low-dose steroid therapy. Deflazacort has been used with a good response and few adverse effects (49).

## 157.8.2 Craniodiaphyseal Dysplasia

Craniodiaphyseal dysplasia is a rare craniotubular remodeling disorder characterized by massive hyperostosis and sclerosis of the skull and facial bones (Figure 157-3), and hyperostosis and defective remodeling of the shafts of the

**FIGURE 157-3** Craniodiaphyseal dysplasia. Boy aged 13 years showing massive hyperostosis of cranium, facial bones, and mandible (leontiasis ossea).

tubular bones. The epiphyses and metaphyses are only mildly affected or spared. The diaphyses are shaped like a policeman's night stick. The early symptoms may be related to respiratory difficulty due to narrowing of the nasal passages (50,51).

**157.8.2.1 Natural History.** Flattening of the nasal root may be noted at birth, and symptoms may occur as early as 3 months of age. Hyperostosis of the cranial and facial bones is progressive in the first years of life, and frank prominence of nasal and adjacent maxillary bones is usually recognized by 1–2 years of age. Symptoms and signs produced by encroachment on cranial foramina including the foramen magnum are marked.

Skeletal radiographs show massive hyperostosis of the cranial bones which develops rapidly during infancy and completely obscures the normal anatomical landmarks. The spine, ribs, clavicles, and scapulae appear hypermineralized but normal in shape. The metaphyses of the long bones are broad and undermodeled. These patients are often of normal-to-tall stature. Serum calcium and phosphorus appear to be normal, but serum alkaline phosphatase is markedly increased.

**157.8.2.2 Genetics.** This disorder is inherited as an autosomal dominant trait in most cases. Autosomal recessive inheritance has been suggested in some cases but the nature of the defect is not known.

**Molecular genetics:** In the autosomal dominant form of craniodiaphyseal dysplasia, heterozygous mutation in the *SOST* gene has been documented in two affected

children. The *SOST* mutations are in the secretion signal of the gene, preventing sclerostin secretion (52).

**157.8.2.3 Management.** There is no effective medical or surgical treatment to prevent the progressive craniofacial hyperostosis and sclerosis and its complications. Some amelioration may be possible with surgical decompression but because of the extreme hyperostosis it is very difficult (53). Special attention should be given to amelioration of hearing and visual impairment and to psychosocial counseling for affected children and their families with this cosmetically disfiguring disorder. As with other craniotubular remodeling disorders, special care must be taken near water as the hyperdense skeleton may contribute to drowning.

### 157.8.3 Endosteal Hyperostosis, Van Buchem Disease, and Sclerosteosis

Endosteal hyperostosis and sclerosteosis are a group of disorders characterized by marked accretion of osseous tissue at the endosteal (inner) surface of bone, leading to narrowing of the medullary canal or obliteration of the medullary space.

**157.8.3.1 Worth Type of Endosteal Hyperostosis.** Worth type is a rare dominantly inherited variety, frequently associated with the presence of a torus palatinus. The torus is a prominent midline ridge of the hard palate in the mouth and is noted in 5% of the population as a normal variant (54). Endosteal hyperostosis predominates in the long bones, but marked hyperostosis of the cranium and lower jaw may occur. This disorder does not always run a benign course, and neurologic involvement may occur (55). Serum alkaline phosphatase may be markedly elevated.

*Molecular genetics:* The disorder can be caused by mutations in *LRP5* on chromosome 11q13.2. Gain-of-function mutations in the amino terminal region of the LDL receptor-related protein 5 (*LRP5*) are responsible (56). Other gain-of-function mutations also result in osteopetrosis indistinguishable from the Albers-Schonberg type apart from an absence of bone fragility. Loss-of-function mutation in *LRP5* is responsible for the osteoporosis-pseudoglioma syndrome.

**157.8.3.2 Van Buchem Type of Hyperostosis.** Hyperostosis corticalis generalisata, or van Buchem disease, is a recessively inherited variety of endosteal hyperostosis, characterized by progressive mandibular enlargement from childhood, and in adult life by signs and symptoms resulting from sclerotic encroachment of optic and acoustic foramina. Serum alkaline phosphatase is markedly elevated. Radiographically, there is marked thickening of the skull, starting in the base and extending to the vault, and increased density of the mandible after puberty. There is increased density of the cortices of tubular bones with narrowing of the marrow cavity.

*Molecular Genetics:* The disease is caused by a 52-kb deletion approximately 35 kb of the sclerostin (*SOST*) gene that removes a *SOST*-specific regulatory element (57). An autosomal dominant form of endosteal hyperostosis can be caused by mutation in *LRP5* (56).

**157.8.3.3 Sclerosteosis.** Sclerosteosis is an autosomal recessive disorder clinically and radiologically almost indistinguishable from van Buchem disease. Sclerosteosis has been differentiated by a high frequency of hyperostosis in the nasal and facial bones, producing a broad flat nasal bridge and ocular hypertelorism with minor hand malformations. The latter consist of cutaneous syndactyly, radial deviation of the second and third fingers, and absent or hypoplastic nails.

**157.8.3.4 Genetics of Van Buchem Disease and Sclerosteosis.** Both van Buchem disease and sclerosteosis result from autosomal recessive inheritance. These are disorders of osteoblast hyperactivity. Genetic studies mapped both to chromosome 17q12–q21. *SOST* is the only gene known to cause sclerosteosis and van Buchem disease (58,59).

Sclerosteosis results from homozygosity for mutation in the *SOST* gene, on chromosome 17q12–q21, which encodes a protein with sequence homology to members of the dan family of secreted glycoproteins. These have been shown to be antagonists of the TGF $\beta$  superfamily (60,61). In a large Dutch family with van Buchem disease, sclerostin downregulation is thought to result from a 52-kb deletion approximately 35 kb downstream of the *SOST* gene which in some way interferes with *SOST* transcription (57).

### 157.8.4 Pachydermoperiostosis

Pachydermoperiostosis, also known as primary hypertrophic osteoarthropathy, is an unusual condition characterized by progressive thickening of the skin and clubbing of the fingers with usual onset in adolescence, although presentation in childhood has been observed. Radiographic findings are similar to those observed in hypertrophic osteoarthropathy associated with chronic pulmonary disease (62).

**157.8.4.1 Clinical Findings.** Those affected develop a massive appearance of the limbs, which may be disproportionately long, and thickening of the facial skin with seborrheic hyperplasia. Complaints of easy fatigability, joint pain, and blepharitis are frequent. The skeletal changes include cortical thickening and sclerosis of the tubular bones, and thickening of the calvaria and base of the skull, which may lead to conductive and/or sensorineural hearing loss, and narrowing of other intervertebral foramina, resulting in neurologic symptoms. Acromegaly has been described in association with pachydermoperiostosis (63).

**157.8.4.2 Genetics.** Pachydermoperiostosis may be genetically heterogenous. Families with vertical transmission consistent with autosomal dominant inheritance

have been observed. The molecular basis of the autosomal dominant form is still unknown. Autosomal recessive inheritance has been documented (64). The autosomal recessive form is molecularly heterogeneous. Homozygous mutations in *HPGD* on 4q34.1 and *ALCO2A1* on 3q22.1–q22.2 have been reported. *HPGD* (NAD(+)-dependent 15-hydroxyprostaglandin dehydrogenase) is the main enzyme of prostaglandin degradation. Homozygous affected individuals develop primary hypertrophic osteoarthropathy secondary to chronically elevated prostaglandin E2 levels (65). Heterozygote relatives also show milder biochemical and clinical manifestations. Mutations in the *HPGD* gene have also been reported in cranio-osteoarthropathy. Using exome sequencing, homozygous mutation in solute-carrier organic-anion-transporter family member 2A1 (*SLCO2A1*), which encodes a prostaglandin-transporter protein, has been identified in a single individual with primary hypertrophic osteoarthropathy (66).

### 157.8.5 Craniometaphyseal Dysplasias

The craniometaphyseal dysplasias (CMDs) are a genetically heterogeneous group of disorders. Both autosomal dominant (Figure 157-4) and recessive inheritance have been described, both groups of patients have overlapping clinical and radiographic findings. In general, recessive CMD has more severe hyperostosis and complications than dominantly inherited CMD.

**157.8.5.1 Natural History.** There is wide variability in the onset of symptoms and signs, but some cases

have been recognized in infancy. Clinically, both dominant and recessively inherited varieties show progressive facial dysmorphism with broad osseous prominence of the nasal root extending across the zygoma (Figure 157-4). Difficulty with breathing and encroachment on the nasal passages may be recognized in the first 6 months of life. Signs and symptoms of sclerotic encroachment on cranial foramina vary in severity from patient to patient but may be unusually severe.

The essential radiologic features are hyperostosis of the skull, nasal, and maxillary bones extending bilaterally across the zygoma with failure of pneumatization of the paranasal sinuses and mastoids and hyperostosis of the mandible. The long bones show flaring and decreased density of the metaphyses (Erlenmeyer flask deformity) due to failure of remodeling of the metaphyses during growth. Hyperostosis and sclerosis of the mandible develop but are less severe than in craniodiaphyseal dysplasia.

**157.8.5.2 Genetics and Molecular Genetics.** The autosomal dominant form of CMD was localized to 5p15.2–p14.1 (67). Dominantly inherited CMD families have mutations in the *ANK* gene, the human homolog of the mouse “progressive ankylosis” (*Ank*) gene. The *ANK* gene codes for a transmembrane protein that regulates the transport of pyrophosphate, an anion which is an important intermediate in bone formation (68). The autosomal recessive form of CMD has been mapped to 6q21–22 (69).

**157.8.5.3 Management.** As in craniodiaphyseal dysplasia, the cosmetic and neurologic problems in craniometaphyseal dysplasia may be considerable. Plastic surgery for the facial hyperostosis and neurosurgery for foramen magnum compression have been successfully performed (70,71).

#### 157.8.5.4 Differential Diagnosis.

##### (1) Craniometadiaphyseal dysplasia, Wormian bone type.

There are several reports of this autosomal recessive syndrome characterized by a large forehead, prominent parietal eminences, and evidence of a mild craniotubular remodeling disorder with sclerosis of the cranial base (72). Serum alkaline phosphatase levels are moderately elevated. In the skull, multiple Wormian bones are present and there is under-tabulation of broad long bones and ribs. This disorder is one in which there is mixed osteosclerosis (skull) and osteopenia. Previous cases of Schwartz–Lelek syndrome are now thought to represent severely affected cases of craniometadiaphyseal dysplasia.

**(2) Oculodentodigital dysplasia (ODD).** This autosomal dominantly inherited disorder combines characteristic facial appearance with microphthalmia hypotrichosis, dental anomalies, fifth finger camptodactyly, and syndactyly between the fourth and fifth fingers with evidence of a mild craniotubular remodeling disorder. There is undermodeling of broad metacarpals

**FIGURE 157-4** Craniometaphyseal dysplasia (autosomal dominant) in woman aged 42, showing hyperostosis of nasal process of frontal bone and adjacent maxilla and mandible.

and phalanges and broad, long tubular bones. ODD results from mutations in the connexin 43 (gap junction protein alpha-I) gene on chromosome 6q21–6q23.2 (73). Autosomal recessive oculodentodigital dysplasia has been identified, due to homozygous *GJA1* gene mutation (74).

### 157.9 CRANIOTUBULAR REMODELING DISORDERS RESULTING FROM MUTATIONS IN FILAMIN A

Vèrloes, in 2000, confirmed the phenotypic overlap noted by previous authors in:

- (1) Frontometaphyseal dysplasia (FMD)
- (2) Otopalatodigital syndrome type I (OPDI)
- (3) Otopalatodigital syndrome type II (OPDII)
- (4) Melnick–Needles syndrome (MNS).

All four disorders, also referred as the otopalatodigital (OPD) spectrum disorders, are characterized by sclerosis of the skull base, and to a varying extent, facial bones. X-linked inheritance has been demonstrated in all four disorders (75). These disorders were mapped to Xq28 and represent a distinct skeletal dysplasia family due to mutations in filamin A (76).

**Molecular pathogenesis:** The filamins are a diverse group of proteins with sequence homology to spectrin, dystrophin, and actinin. Filamin A encodes a 280 kDa protein characterized by actin-binding domains (ABD), which interact with F-actin, and two calponin homology domains (CHD1 and CHD2), and regulates reorganization of the actin cytoskeleton. Mutations that lead to the OPD spectrum disorders occur in defined regions of the filamin A protein, suggesting that very specific functions are being altered in these disorders (56). Heterozygous nonsense and frameshift mutations in the filamin A gene can result in periventricular nodular heterotopia, an X-linked dominant male lethal seizure disorder.

#### 157.9.1 Frontometaphyseal Dysplasia

Frontometaphyseal dysplasia produces a clinically striking facial appearance with a pronounced supraciliary ridge resulting from a torus-like bony overgrowth of the frontal bones (Figure 157-5).

**157.9.1.1 Clinical Findings.** The prominent supra-orbital ridge, which extends across the entire frontal bone, may be recognized at birth, although in some cases not until later. It is associated radiographically with poor development of the frontal and other paranasal sinuses and with mandibular hypoplasia. The pelvis shows an unusually abrupt flare. There is marked frontal hyperostosis and variable hyperostosis of long tubular bones. Metaphyses of the long bones are under-modeled resulting in an Erlenmeyer flask appearance. The bones of the hands and feet are under-tubulated.

**FIGURE 157-5** Frontometaphyseal dysplasia. Boy aged 12 years showing torus-like hyperostosis of frontal bone extending across cranium.

Frontometaphyseal dysplasia should be distinguishable from Sphrintzen–Golberg syndrome, in which there are similar modeling defects in short tubular bones. Hirsutism, obstructive uropathy, congenital stridor, and conductive deafness have been observed. Scoliosis with various alterations of the modeling of the tubular bones may be present.

**157.9.1.2 Genetics.** The disorder is inherited as an X-linked dominant trait (77). Females are more mildly affected than males and have features similar to osteodysplasty. There is significant phenotypic overlap between patients with frontometaphyseal dysplasia and otopalatodigital syndrome (OPD).

Frontometaphyseal dysplasia results from missense mutations in the filamin A gene. Sequence analysis of the *FLNA* gene detects mutations in 57% of affected individuals with FMD (56).

#### 157.9.2 Otopalatodigital Syndrome Type I

Otopalatodigital syndrome is characterized by short stature, and characteristic face with prominent supra-orbital ridges and broad flattened nasal bridge. There is a high frequency of conductive hearing loss. The feet are characteristic, with a short, broad first toe, wide first interdigital space, and varus of all toes that

are terminally short and expanded. Sequence analysis detects mutations in the *FLNA* gene in 43% of individuals with OPDI (56).

**157.9.2.1 Molecular Genetics.** In this group of patients, missense mutations in the filamin A gene are clustered in the CHD2 domain. Again, a number of recurrent missense mutations, such as P207L, have been observed.

### 157.9.3 Otopalatodigital Syndrome Type II

Short stature is of prenatal onset and recognized on prenatal ultrasound. Dysmorphic features include hypertelorism, frontal bossing, broad nasal bridge, and usually wide anterior fontanelle present with cleft palate. The hands are distinctive, with broad, short thumbs and often overlapping fingers. Radiographs show broad undermodeled phalanges and abnormal metacarpals that have geometric segmental shapes reminiscent of atelosteogenesis III (a disorder that results from mutations in filamin B). There is variable syndactyly of fingers and toes. The femora are bowed laterally and tibiae are bowed medially with hypoplasia of fibulae. Osteosclerosis is present in the skull base.

**157.9.3.1 Molecular Genetics.** The recurrent mutation, E254K, in the filamin A gene has been found in all cases of OPDII with omphalocele. This mutation is predicted to interfere with a conserved salt bridge with lysine 169. Other missense mutations have been found in cases without omphalocele in regions of filamin important in actin binding. Sequence analysis of the *FLNA* gene detects 69% of individuals with OPDII (56).

### 157.9.4 Osteodysplasty (Melnick–Needles Syndrome)

Melnick–Needles syndrome (MNS) is characterized by abnormal thinning and irregular narrowing of ribs and long bones.

**157.9.4.1 Clinical Findings.** The age at diagnosis is variable, and affected individuals usually present because of an abnormal gait with bowing of the extremities. Occasionally, dislocation of hips or delayed closure of the anterior fontanelle occurs. On the whole, these patients do not have short stature, and psychomotor development and adult height are normal. Facial appearance is somewhat typical, with slight exophthalmos, protruding cheeks, a high narrow forehead, prominent orbital rims, micrognathia, and misaligned teeth. The lower thorax is narrow. There is incurving of the distal segments of the thumbs. Congenital urinary tract anomalies and heart defects occur relatively frequently and are consistently found in affected males.

Radiographically, there is uneven thickening of the cortex of long bones, which have irregular contours and multiple constrictions, producing a wavy border. The diaphyses are slightly curved and show metaphyseal modeling defects. There is sclerosis of the cranial

base. Coxa valga and dislocation of the hips is frequent. The ribs appear wavy, the pelvis is triangular, and the iliac wings appear to be narrowed in their lower third.

**157.9.4.2 Genetics.** Osteodysplasty is inherited as an X-linked dominant trait with severe disease or infant lethality in males. Robertson et al. (1997) described a family with male otopalatodigital syndrome type II, in which female heterozygotes had skeletal changes characteristic of mild Melnick–Needles syndrome (78).

**157.9.4.3 Molecular Genetics.** Two recurrent mutations within exon 22, A1188T and S1199L, were reported in 12 unrelated families with Melnick–Needles syndrome. Both mutations resulted from separate de novo mutation events (56). Sequence analysis of the *FLNA* gene detects 100% of affected individuals (56).

**157.9.4.4 Differential Diagnosis.** Frank-ter-Haar syndrome. This autosomal recessive (AR) disorder has been referred to as a severe AR osteodysplasty in view of the findings of caliber variation of ribs and bowed long bones similar to those seen in MNS. Males and females are affected. Dysmorphic features include megalocornea/congenital glaucoma, large anterior fontanelles, prominent coccyx with a skin fold in the natal cleft, and congenital heart defects (79). Homozygous mutations in *TKS4* (podosome adaptor gene) on chromosome 5q35 have been associated with Frank-ter-Haar syndrome (80).

## 157.10 TUBULAR STENOSIS (KENNY–CAFFEY SYNDROME)

Tubular stenosis is characterized by narrowing of the medullary cavity and hypermetropia or myopia. In some patients, tetanic seizures due to hypocalcemia occur in infancy (81,82).

### 157.10.1 Clinical Findings

Medullary stenosis may be recognized at an incidental radiographic study or as part of the investigation of the infant with clinical manifestations of hypocalcemia. Other clinical features include delayed closure of the anterior fontanelle and early-onset hypermetropia, myopia, or optic atrophy.

Radiographically, there is a widening of the cortex in the long bones and short tubular bones of the hands and feet, without overall widening of the diaphyses, leading to reduction of the medullary cavity. Rarely, vertebrae, pelvis, carpals, tarsals, and skull may show increased density.

### 157.10.2 Genetics

Both an autosomal dominant syndrome of medullary stenosis and hypocalcemia and an autosomal recessive syndrome have been reported.

### 157.10.3 Molecular Genetics

Autosomal recessive Kenny–Caffey syndrome (AR-KCS) results from mutations in the tubulin-specific chaperone E (TBCE) gene, mapped to 1q42 (83). Mutations in *TBCE* result in abnormal tubulin assembly. Mutations in *TBCE* also account for the Sanjad–Sakati syndrome of autosomal recessive congenital hypoparathyroidism (83).

### 157.10.4 Differential Diagnosis

Tubular stenosis is regularly seen in the Down syndrome newborn skeleton, where it is misinterpreted as osteosclerosis.

## 157.11 HYPERPHOSPHATASEMIA WITH OSTEOECTASIA

In hyperphosphatasemia with osteoectasia, progressive skeletal deformation is associated with marked elevation of alkaline phosphatase. As the clinical and radiologic findings resemble Paget disease, it has sometimes been known as juvenile Paget disease, hyperostosis corticalis deformans juvenilis or familial idiopathic hyperphosphatasia.

### 157.11.1 Clinical Findings

The disease usually has its onset between 2 and 3 years of age, when painful deformity of the extremities develops and leads to gait abnormalities and sometimes fractures. The clinical findings are similar to those of Paget disease in adults but are more generalized and symmetric in distribution. Short stature ultimately results. The skull is large, and radiographically, the diploe is widened and there is loss of normal calvarial structure. Bony texture is variable with dense areas (showing a teased cotton–wool appearance) interspersed with lucent areas. Marked demineralization is seen throughout the remainder of the skeleton. The long bones appear cylindrical, even fusiform, and deformed with the loss of normal metaphyseal modeling. Pseudocysts with a dense bony halo may be seen throughout the long bones. Clinical response has been observed with experimental treatment with recombinant osteoprotegerin (84).

### 157.11.2 Genetics and Molecular Genetics

The disorder is inherited as an autosomal recessive trait. Juvenile Paget disease results from homozygous mutations in the tumor necrosis factor receptor superfamily, member 11B (*TNFRSF11B*) gene (85,86). Mutations in the *TNFRSF11B* gene on chromosome 8q24 that encodes osteoprotegerin, a regulator of osteoclastogenesis, account for the majority of cases with idiopathic

hyperphosphatasemia (87). In normal bone, osteoprotegerin suppresses bone turnover by acting as a decoy receptor for RANK ligand (osteoclast differentiation factor) and this function is disrupted by the known mutations in osteoprotegerin.

### 157.11.3 Management

Clinical and radiographic amelioration of the skeletal lesions after treatment with intravenous pamidronate (similar to the regimen used for osteogenesis imperfecta) has produced encouraging results.

## 157.12 DISORDERS OF PARATHYROID HORMONE RESISTANCE

It is usual to subdivide pseudohypoparathyroidism into the following disorders, which have significant overlap in phenotypic features, but distinctive endocrine and biochemical findings:

- (1) Pseudohypoparathyroidism type I
  - (a) Type Ia
  - (b) Type Ib
  - (c) Type Ic
- (2) Pseudo-pseudohypoparathyroidism
- (3) Pseudohypoparathyroidism type II

Synonyms: pseudohypoparathyroidism (PHP), pseudo-pseudohypoparathyroidism (PPHP), parathyroid resistance syndromes.

### 157.12.1 Clinical Findings

Pseudohypoparathyroidism (PHP) describes a group of disorders characterized by biochemical hypoparathyroidism (i.e. low serum calcium and elevated serum phosphate), increased serum concentrations of parathyroid hormone (PTH), and end-organ resistance to the biological actions of PTH (88).

The clinical findings commonly associated with PHP disorders are disproportionate short stature with acrodysplasia (selective distal shortening of tubular bones, predominantly of metacarpals but also of metatarsals and phalanges), and a round face and obesity. Collectively, these features are termed Albright's hereditary osteodystrophy (AHO). There is also a high frequency of mental retardation and ectopic, usually subcutaneous, calcification (88).

In pseudo-pseudohypoparathyroidism (PPHP) (89), subjects have the somatic features of AHO in the presence of normal serum chemistries and normal end-organ responsiveness to exogenous PTH.

As PHP and PPHP are often both found in the same family, it is likely that they represent variability within the same dominant genetic disorder (see Section 157.12.3).

### 157.12.2 Natural History

In pseudohypoparathyroidism type I, symptomatic hypocalcemia may be the presenting sign. Seizures, tetanic episodes, and evidence of ectopic or intracranial calcification may also bring a child to attention. The serum calcium may be normal in childhood and decrease with age. Mental retardation or a family history of short stature and mental retardation may be recorded. Affected individuals develop short stature with moderate obesity and dental anomalies. These consist of delayed eruption, enamel hypoplasia, dentin hypoplasia, and teeth with short blunt roots.

In PHP type Ia and PPHP, short digits arise from early closure of the epiphyses of the short tubular bones of the hands. The fourth and fifth digits are most often involved and the second least of all. The commonest phalanx affected is the distal first, due to premature closure of its epiphysis. The findings are virtually identical to those seen in brachydactyly type E and some females with Turner syndrome. Cone-shaped epiphyses may be seen at the base of both first metacarpals. Many subjects will also have unusual forms of spinal canal stenosis affecting any region of the spine, but particularly the cervical and/or lumbar spine. These features are similar to those encountered in cheirolumbar dysostosis and there may again be overlap in pathogenesis between subjects with PPHP and cheirolumbar dysostosis.

Other skeletal anomalies include scoliosis, radius curvus, cubitus valgus, coxa valga and vara, and genu valgum and varum. Ectopic calcification usually appears in infancy and may be located in any site, but most commonly in the extremities around large joints.

Mental retardation is present in some 75% of cases with PHP. The mean IQ is in the order of 60. Mental retardation is strongly correlated with the finding of hypocalcemia at presentation, occurring in 70% of affected with hypocalcemia, but only 30% of normocalcemic patients. Lenticular opacities have been reported in 44% of patients.

Endocrine abnormalities associated with PHP include hypothyroidism, hypogonadism, growth hormone deficiency, and diabetes mellitus.

### 157.12.3 Genetics and Pathogenesis

Many of the actions of PTH on kidney and bone are mediated through cAMP. In normal subjects, the administration of exogenous PTH significantly increases renal cAMP production and urinary cAMP levels. The PTH infusion test allows for the various forms of PHP to be distinguished on biochemical grounds. In PHP type I, exogenous PTH fails to cause an increase in urinary cAMP or phosphate, whereas in PHP type II, PTH causes normal urinary cAMP but impaired phosphate excretion (88).

In PHP type I, serum and urinary cAMP generation by endogenous PTH is defective, which initially suggested a defect in PTH binding or transduction at the PTH/PTHrP receptor in the pathway of generation of cAMP. Coupled transduction at the PTH/PTHrP receptor is mediated by guanine nucleotide-binding regulatory proteins (G-proteins). There are both G<sub>s</sub> (stimulatory) and G<sub>i</sub> (inhibitory) proteins. The characterization of the G proteins has shown that in most patients with PHP type I, it is the G<sub>s</sub>- $\alpha$  protein subunit of the adenylate cyclase receptor complex that is defective. The gene that encodes this protein, *GNAS1*, is located on chromosome 20q13.3. Studies into the activity of the G<sub>s</sub>- $\alpha$  protein subunit have allowed for subjects with PHP type I to be subdivided into two distinct groups: PHP type Ia (those with G<sub>s</sub>- $\alpha$  protein subunit deficiency) and PHP type Ib (those with normal levels of G<sub>s</sub>- $\alpha$  protein subunit). The G<sub>s</sub>- $\alpha$  protein subunit receptor complex is also important for the transduction of other hormones. As such, in addition to PTH resistance, patients with PHP type Ia may have resistance to thyroid-stimulating hormone (TSH), gonadotropins, glucagon, calcitonin, and growth hormone. Subjects with PHP type Ib have isolated PTH resistance (occasional mild TSH resistance) without the features of AHO. Subjects with PHP type Ic have the biochemical and clinical features of PHP type Ia, but lack a demonstrable abnormality of G<sub>s</sub> or G<sub>i</sub> (88). Linglart et al. found functional defects of G<sub>s</sub>- $\alpha$  in subjects with PHP type Ic, which would not be apparent on current in vitro assays (90).

PHP type II is a rare disorder with an uncertain etiology and inheritance. Subjects with PHP type II have a reduced phosphaturic response, but a normal cAMP response to exogenous PTH (88). This disorder may result from the inability of cAMP to activate downstream targets within the kidney, or be secondary to PTH resistance in patients with severe and unsuspected vitamin D deficiency (88).

### 157.12.4 Molecular Pathogenesis of PHP Type Ia, PPHP, and PHP Type Ib

Subjects with PHP type Ia have (1) the biochemical findings of PHP, (2) the phenotypic features of AHO, and (3) multiple endocrine resistances. This disorder is caused by mutations of *GNAS1* on chromosome 20q13.3, which results in a reduction in G<sub>s</sub>- $\alpha$  protein subunit activity. The same mutation also results in PPHP, a disorder characterized by AHO but normal sensitivity to PTH and other hormones (91). Both disorders are frequently observed within the same kindred. *GNAS1* is a highly imprinted gene, with the development of PHP type Ia or PPHP being dependent on the gender of the parent transmitting the mutant allele (91). If the *GNAS1* mutation is inherited from a male with either PHP type Ia or PPHP, the affected offspring will all have PPHP. If the same mutation is

transmitted from a female with either of these disorders, then the affected offspring will all have PHP type Ia. Patients with PPHP generally coexist with PHP type Ia in the same family but never in the same sibship (92). Despite the Gs- $\alpha$  subunit being a ubiquitously expressed signaling protein, the hormone resistance associated with PHP type Ia is limited to only a few tissues. These observations, together with the imprinting described above, suggest that Gs- $\alpha$  mRNA from one parental allele is transcribed in certain hormone-responsive cells/tissues (93). It is postulated therefore, that hormone resistance only results from heterozygous Gs- $\alpha$  mutations in cells/tissues where there is monoallelic Gs- $\alpha$  subunit expression (93). In other tissues, 50% reduction in Gs- $\alpha$  levels result in haploinsufficiency; this AHO develops regardless of the gender of the parent transmitting the defect (92). Further work is required to clarify this.

To add further complexity, *GNAS1* has multiple transcriptional units (91). The Gs- $\alpha$  subunit is encoded by exons 1–13. A second transcript, *XL<sub>2s</sub>*, has a novel first exon (XL) that splices onto exons 2–13 and is transcribed only from the paternal allele. In vitro it functions as a stimulatory G protein. A third transcript, *NESP55*, is located upstream of exon XL and the Gs- $\alpha$  subunit exons. *NESP55* is expressed from the maternal allele and is a chromogranin-like neuroendocrine secretory protein. Two other transcripts A/B and AS have been identified. A/B is expressed on the paternal allele. Its promoter and first exon is 2.5 kb upstream of Gs- $\alpha$  (94).

PHP type Ib is an autosomal dominant disorder characterized by renal resistance to PTH (occasional mild TSH resistance) without any features of AHO. Some individuals may show the skeletal features of hyperparathyroidism (91). PHP type Ib does not result from mutations in the exons encoding Gs- $\alpha$  or the PTH/PTHrP receptor (93). The genetic defect in PHP type Ib appears to be paternally imprinted and inherited in a manner similar to the PTH-resistance of PHP type Ia and PPHP. Family studies suggest that PHP type Ib results from a mutation in a putative *cis*-acting element involved in the methylation imprinting at *GNAS1* exon A/B (93).

### 157.12.5 Differential Diagnosis

- (1) **Causes of hypoparathyroidism and hypocalcaemia.** These include both primary and secondary hypoparathyroid states and are excellently reviewed by Bastepe et al. (94).
- (2) **Syndromes of mental retardation, obesity, short stature, and brachydactyly.** These include Turner syndrome (45, X gonadal dysgenesis), basal cell nevus syndrome (Gorlin's syndrome), Gardner syndrome, and type E brachydactyly (95).
- (3) **Chromosome deletion 2q37.3 syndrome.** A subgroup of patients with deletion 2q37 detected

by subtelomeric fluorescence in situ hybridization (FISH) have mild intellectual disability and features of AHO with short metacarpals. This subgroup commonly has deletion 2q37.3. This chromosome region contains the gene for GPR35, a member of the G protein coupled receptor superfamily (96).

- (4) **Czech dysplasia—metatarsal type.** Progressive shortening of metacarpals and metatarsals is found in adults and presumably commences during childhood. Otherwise this bone dysplasia shows a severe spondyloarthropathy with marked narrowing of joint spaces (97). The thoracic spine shows marked platyspondylia and lumbar spine is relatively spared. Markers of bone formation are elevated. Czech dysplasia is inherited as an autosomal dominant trait. It is thought to be a common bone dysplasia in Czechoslovakia and neighboring countries. A heterozygous (R75C) mutation in the *COL2A1* gene on chromosome 12q13 has been identified in studied individuals (98,99).

### 157.12.6 Management

The basic principles of treatment are the same as those for the management of hypoparathyroidism. The aim is to maintain low-normal serum calcium concentrations with supplementary dietary calcium and vitamin D, thus avoiding symptoms of tetany while minimizing hypercalciuria. With treatment, the serum phosphorus usually returns to the high normal range. The serum calcium can fluctuate, which can result in periods of lethargy, especially during childhood. This often improves with calcitriol therapy. Treatment does not prevent the progression of lenticular opacities but may improve mental functioning.

Estrogen may significantly influence serum calcium concentration in females with PHP (88). Decreased serum calcium is associated with estrogen therapy and at the time of menses in women with both PHP and hypoparathyroidism. During pregnancy, however, the requirement for vitamin D therapy in some women with PHP decreases significantly. This may be due to placental production of 1,25-dihydroxyvitamin D (88).

Patients with PHP type Ia will frequently have multiple hormone resistance. As such, their endocrine status requires regular monitoring and if indicated, replacement therapy started.

## 157.13 X-LINKED HYPOPHOSPHATEMIC RICKETS

X-linked hypophosphatemic rickets (XLH) is the most common heritable form of rickets, with a prevalence of 1:20,000 (100). It is a renal phosphate wasting disorder characterized by rickets resistant

to vitamin D therapy, a low serum phosphate, and an inappropriately normal 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D). (Synonym: X-linked vitamin D-resistant rickets.)

### 157.13.1 Clinical Findings

Children with XLH exhibit short stature, rickets, lower extremity deformity (genu varum or valgum), and dental abscesses. Growth delay is often present within the first few months of life, but the lower extremity bowing may not develop until the child commences weight bearing. Adults typically have osteomalacia and may develop bone pain, joint stiffness, and overgrowth of bone at the site of muscle attachments (enthesopathy). Enthesopathy may result in joint limitations and various neurologic compressive syndromes.

There is significant variability in the phenotype, ranging from patients with only hypophosphatemia to those with a combination of hypophosphatemia, short stature, and rickettic bone changes. Affected females may have less severe radiological and dental abnormalities and tend to respond better to therapy (100). Although growth rate is consistently disturbed, following the commencement of therapy the growth of children with XLH generally parallels the normal growth curves (101). In some mildly affected individuals, growth may accelerate at puberty and cross the third percentile. In others, the growth spurt of puberty may aggravate bowing of the legs.

Dentition may be late, and abnormal development of the maxillofacial region has been reported. Spontaneous dental abscesses occur in the primary dentition of 25% of children (102), and 85% of adults reporting dental problems (103).

In adults, bowing of the legs and short stature may persist. In some patients, evidence of active osteomalacia may be present. Overgrowth of bone at the site of muscle attachments (enthesopathy) may lead to joint limitations and various neurologic compressive syndromes.

### 157.13.2 Genetics

XLH is inherited as an X-linked dominant trait. Because there is no father-to-son transmission, it is expected that there would be twice as many females as males affected (104). Males with XLH have been reported as having more severe radiological and dental abnormalities than females (102,105). This was attributed to random X-chromosome inactivation in females (the Lyon hypothesis), with a gene dose effect. Subsequent clinical and animal studies have questioned these initial findings (104,106). In a review of 30 children with XLH, Whyte et al. found no evidence to support a gene dose effect and suggested that the different severity was secondary to such factors as sex hormones and physical activity (104).

### 157.13.3 Molecular Pathology

XLH results from impaired renal phosphate reabsorption, inadequate 1,25-dihydroxyvitamin D response to hypophosphatemia, and an intrinsic osteoblast defect (100). Mutations in the phosphate-regulating endopeptidase homolog gene (*PHEX*) on chromosome Xp22.11 are associated with XLH (100). Numerous mutations have been reported in *PHEX* (101). The spectrum of mutations includes a majority of missense (34%), nonsense (27%), deletion (16%), and splicing mutations (15%). Despite much research, the exact mechanism by which *PHEX* mutations result in XLH remains to be elucidated.

The human gene *PHEX* encodes a 749-amino-acid polypeptide with 96% homology to its murine counterpart. It is a membrane-bound zinc metallopeptidase expressed predominantly in fetal bone (osteoblasts), teeth (odontoblasts), and growth-plate cartilage (chondrocytes) (100). It is not, however, expressed in the proximal renal tubule, the site of phosphate reabsorption. These data lead to the hypothesis that a circulating factor (a phosphatonin) regulated by *PHEX* influences renal phosphate homeostasis and impairs 1,25(OH)<sub>2</sub>D metabolism. This hypothesis was supported by parabiosis and cross-transplant experiments between wild-type and Hyp mice (107–109).

The most likely candidate phosphatonin is fibroblast growth factor 23 (FGF-23), which both in vivo and in vitro has been demonstrated to inhibit renal phosphate transport, inhibit the formation of 1,25-dihydroxyvitamin D, and is associated with tumor-induced osteomalacia (74). Other possible phosphatonins include matrix extracellular phosphoglycoprotein (MEPE) and secreted frizzled related protein 4 (sFRP4) (100).

There is also an intrinsic osteoblast defect present in XLH, which is not resolved by treatment with phosphate and calcitriol (100). This may explain why adequate treatment does not completely normalize the growth and skeletal deformity of subjects with XLH.

### 157.13.4 Management

The goal of treatment in XLH is to maximize growth and minimize skeletal deformity. Oral supplementation with phosphate combined with vitamin D is effective in achieving these goals, although the normalization of stature is not always possible (110). An acidic oral phosphate supplement has been recommended as this is better tolerated. For maximum benefit, phosphate must be given in five divided doses at 3–4 h intervals both day and night. This is an arduous treatment regime, but the benefits gained justify the approach. Phosphate therapy alone leads to the development of secondary hyperparathyroidism (110). Calcitriol (1,25-dihydroxyvitamin D<sub>3</sub>) has been shown to be particularly effective in correcting the growth disorder in XLH and is the vitamin D of choice in the management of XLH.

Although rachitic changes and reduced growth are noted within the first year of life, treatment with phosphate and calcitriol is often delayed until 12 months of age, when weight bearing begins. The treatment regime is phosphate 100 mg/kg/dose, five times a day, and calcitriol 0.25 µg twice daily. The phosphate dose can be reduced within a month or so. Bloods should be drawn for calcium, alkaline phosphatase, and PTH levels 2 weeks after starting treatment. The urine calcium:creatinine ratio should also be monitored. Children should be seen every 3 months to monitor their serum and urine biochemistry and growth. A renal ultrasound should be performed annually to evaluate for nephrocalcinosis. Renal impairment is a rare complication of nephrocalcinosis when it does occur. An annual bone age is useful to monitor for rachitic changes and skeletal maturity.

Surgical osteotomy has a valuable role in correcting residual deformity of the lower limbs, usually during puberty.

### 157.13.5 Differential Diagnosis

- (1) **Autosomal dominant hypophosphatemic rickets (ADHR).** Like XLH, ADHR is disorder associated with isolated renal phosphate wasting and inappropriately normal 1,25-dihydroxyvitamin D concentrations (111). There is, however, significant phenotype heterogeneity with regards to age of onset and severity of skeletal deformities and incomplete penetrance in ADHR (111). Further, two patients have been reported who appeared to lose their renal phosphate defect, making ADHR the only genetic hypophosphatemia disorder where this has been described (112). ADHR results from mutations in the *FGF23* gene on chromosome 12p13 (113), which result in increased biological activity of FGF-23 (114).
- (2) **Autosomal recessive hypophosphatemic rickets (ARH1 and ARH2).** Two autosomal recessive types have been described. Type 1 is caused by mutations in the *DMP1* gene on chromosome 4q22.1 and type 2 is caused by mutations in *ENPP1* gene on chromosome 6q23.3 (115,116).
- (3) **Tumor-induced osteomalacia (TIO).** TIO has similar clinical and biological features to XLH. This disorder is, however, acquired, and often manifests with significant bone and muscle pain, out of keeping with the physical and radiological findings. The serum alkaline phosphatase may be more elevated than observed in XLH and ADHR (100). Unlike in XLH and ADHR, the 1,25-dihydroxyvitamin D in TIO is frequently low, which results in hypocalcemia and secondary hyperparathyroidism (100). The most common tumor associated with TIO is a phosphaturic mesenchymal tumor, mixed connective tissue variant (PMTMCT). These are slow growing benign tumors that are otherwise asymptomatic, and are often difficult to identify due to their small size and obscure location (100). Removal of the tumor results in rapid resolution of the disorder. Patients with fibrous dysplasia, neurofibromatosis, and linear nevus sebaceous syndrome may also develop significant hypophosphatemia and osteomalacia, which may be mediated by FGF-23 (117).
- (4) **Vitamin-D-dependency rickets (VDD).** This syndrome appears to be biochemically heterogenous, with two forms presently delineated (see Chapter Disorders of the Body Mass).
  - (a) **Autosomal recessive VDD rickets.** These patients have early infancy onset of hypocalcemia, normal or low serum phosphorus, elevated serum alkaline phosphatase, generalized aminoaciduria, and clinical and radiographic findings of severe rickets. Serum 25-hydroxyvitamin D is normal, but serum 1,25-dihydroxyvitamin D is below the limits of detection (118). The disorder results from defective 1-hydroxylation of 25-hydroxyvitamin D due to mutations in the 1-α-hydroxylase gene (119) (see Chapter Disorders of the Body Mass).
  - (b) **Target organ resistance to 1,25-dihydroxyvitamin D.** Brooks et al. (1978) reported a 22-year-old black patient with symptomatic osteomalacia, hypocalcemia, and hyperaminoaciduria from the age of 15 years (120). In this patient, plasma 25-hydroxyvitamin D was markedly increased. Osteomalacia in the face of elevated serum 1,25-dihydroxyvitamin D is thought to be due to impaired target organ responsiveness (see Chapter Genetic Lipodystrophies).

Service of Medical Genetics, Lausanne, Switzerland

### 158.1 INTRODUCTION

The skeletal dysplasias are a heterogeneous group of disorders associated with abnormalities in the size and shape of the limbs, trunk, and/or skull that frequently result in disproportionate short stature. Until the 1960s, most disproportionate dwarfs were considered to have either achondroplasia (those with short limbs) or Morquio disease (those with a short trunk). It is now apparent that there are well over 450 distinct skeletal dysplasias, which have been classified primarily on the basis of their clinical or radiographic characteristics (see [Table 158-1](#) and [Further Reading](#)).

### 158.2 CLASSIFICATION AND NOMENCLATURE

Current nomenclature for the chondrodysplasias is somewhat confusing and is based on (1) the part of the skeleton that is affected radiographically (e.g. the metaphyseal dysplasias) or clinically and/or radiographically (e.g. the acromesomelic dysplasias); (2) a Greek term that describes the appearance of the bone or the course of the disease (e.g. diastrophic (twisted) dysplasia, thanatophoric (death-seeking) dysplasia); (3) an eponym (e.g. Kniest dysplasia, Ellis-van Creveld syndrome); or (4) a term that attempts to describe the pathogenesis of the condition (e.g. achondroplasia, osteogenesis imperfecta) or the gene implicated (e.g. SEMD, Aggrecan type).

The extent of the heterogeneity in these disorders and the variety of methods used for their classification have resulted in further confusion. Clinical classifications have divided the skeletal dysplasias into those with short-limbed dwarfism, and those with short-trunk dwarfism. The short-limbed varieties have been further subdivided on the basis of the segment of the long bones that is most severely involved. Other clinical classifications have been based on the age of onset of the disorder, and those disorders that manifest themselves at birth (achondroplasia)

versus those that first manifest in later life (e.g. pseudoachondroplasia). Although this information is occasionally still useful in describing various skeletal dysplasias and in arriving at a diagnosis, the advent of nearly universal prenatal ultrasound examinations has altered our perception of the timeline and revealed this criterion to be often subjective in nature. Associated clinical abnormalities have also been used to subdivide these disorders. Examples are the myopia of spondyloepiphyseal dysplasia congenita, the cleft palate of Kniest dysplasia, the fine hair of cartilage-hair hypoplasia, and the polydactyly and congenital heart disease of the Ellis-van Creveld syndrome. Still other disorders have been classified on the basis of their apparent mode of inheritance, for example the dominant and X-linked varieties of spondyloepiphyseal dysplasia.

The most widely used method of differentiating the skeletal dysplasias has been the detection of skeletal radiographic abnormalities. Radiographic classifications are based on the different parts of the long bones that are abnormal (epiphyses, metaphyses, or diaphyses) ([Figures 158-1 and 158-2](#)). Thus there are epiphyseal and metaphyseal dysplasias, which can be further divided depending on whether or not the spine is also involved (spondyloepiphyseal dysplasias, spondylometaphyseal dysplasias). Furthermore, each of these classes can be further divided into several distinct disorders based on a variety of other clinical and radiographic differences.

In an attempt to develop a uniform nomenclature and classification system for these disorders, an International Nomenclature of Constitutional Diseases of Bone was proposed in 1970 and updated in 1977, 1983, 1992, 1997, 2001, 2006, and 2010.

As short stature is a frequent finding in these disorders, the term “dwarfism” has been historically used for them. However, “dwarfism” is thought to result in stigmatization and is popularly unappealing, and for these and other reasons, the term “dwarfism” has been dropped from the current nomenclature and replaced by the term dysplasia. This latter term, which means “disordered growth,” reflects the probable pathogenesis of the majority of the chondrodysplasias. In contrast, malformations

<sup>†</sup>Deceased.

**TABLE 158-1 Clinical, Radiologic, Morphologic, and Genetic Features in the Chondrodysplasias (Associated with Defects of Growth of Tubular Bones and/or Spine)**

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
<b>Achondroplasia group</b>							
Thanatophoric dysplasia, type I (includes platyspondylic lethal, San Diego type)	Large, bulging forehead, prominent eyes, depressed nasal bridge, wide fontanelles and sutures	Small, narrow, pear-shaped	Micromelia	Hydrocephalus, congenital heart and CNS defects	Large calvaria, short base, small foramen magnum; infrequent craniosynostosis	Short, cupped and splayed anteriorly	Hypoplastic, inverted U-shaped (AP), marked flattening with round anterior end (lateral)
Thanatophoric dysplasia, type II	Cloverleaf skull	Small, narrow, pear-shaped	Micromelia		Cloverleaf skull	Short, cupped and splayed anteriorly	Platyspondylia less severe than type 1
Achondroplasia	Large head, bulging forehead, low nasal bridge, prominent mandible	Slight rib flaring	Rhizomelic shortening, fatty folds of skin in infancy, genu varum	Early otitis media, spinal stenosis	Large calvaria, short base, small foramen magnum	Short, cupped anteriorly	Decreased lumbosacral interpedicular distance, short pedicles
Hypochondroplasia	Normal head to slight prominence of forehead	Normal-mild lumbar lordosis	Rhizomelic shortening of extremities, short broad hands, limited extension at elbow	Mild short stature, muscular appearance	Normal	Normal to slightly flared anteriorly	Lumbosacral interpedicular narrowing, short pedicles, posterior scalloping
SADDAN (severe achondroplasia with developmental delay and acanthosis nigricans)	Severe midface hypoplasia, frontal bossing	Small chest	Rhizomelic shortening, fatty folds of skin persisting to childhood	Developmental delay, structural CNS anomalies, acanthosis nigricans	Large calvaria, no craniosynostosis	Short	Platyspondylia, decreased lumbosacral interpedicular distance, short pedicles
Osteoglophonic dysplasia	Prominent supra-orbital ridge, depressed nasal bridge, short neck	Normal	Rhizomelic shortening	Delayed tooth eruption	Craniosynostosis	Progressive rib expansion	Normal
<b>Type II Collagenopathies</b>							
Achondrogenesis II/ hypochondrogenesis (Langer-Saldino)	Round flat face, short neck	Short, barrel-shaped	Very short	Distended abdomen, fetal hydrops	Large calvaria, posterior ossification defect	Very short ribs	Absent or minimal vertebral ossification (thoracolumbar)
Kniest dysplasia	Flat face, prominent wide-set eyes, broad nasal root	Short trunk	Short, prominent knees, joint contractures	Myopia, retinal detachment, hearing loss	Frontal flattening, maxillary hypoplasia, shallow orbits	Short	Diffuse flattening, coronal clefts
Spondyloepiphyseal dysplasia congenita, type Spranger-Wiedemann (SEDC)	+/- Round flat face, short neck, prominent eyes, +/- cleft palate	Short barrel chest, pectus carinatum	Mild rhizomelic shortening, normal hands, +/- club feet	+/- Myopia, retinal detachment, hearing loss, subluxation of C1-C2	Relatively normal	Short	Flattened, dorsal wedging (pear-shaped); odontoid hypoplasia

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Small, short, flat spiculated acetabulum; small sacrosciatic notch	Short, bowed femora +/- bowing of other bones, metaphyseal flaring (with medial spike-femora)	Generalized disruption of growth plate, poor columns, fibrous bands and fibrous ossification; large RER <sup>a</sup> inclusion bodies in fetus	AD	4p16.3	<i>FGFR3</i>	FGFR3	187600
Small, short, flat spiculated acetabulum; small sacrosciatic notch	Straight femora	Generalized disruption of growth plate, poor columns, fibrous bands and fibrous ossification	AD	4p16.3	<i>FGFR3</i>	FGFR3	187601
Squared-off ilia, small sacrosciatic notches	Short, broad; oval radiolucency in proximal femora in infancy; relative overgrowth of fibulae	Chondrocytes normal and growth plate regular, periosteal overgrowth	AD	4p16.3	<i>FGFR3</i>	FGFR3	100800
Slightly short basilar segments of ilia	Rhizomelia with short, wide bones, prominent deltoid tubercles, elongated fibulae	Normal growth plate	AD	4p16.3	<i>FGFR3</i> some families not linked to <i>FGFR3</i>	FGFR3	146000
Similar to achondroplasia	Severe rhizomelic shortening, neonatal tibial and fibular bowing	Short proliferative and hypertrophic zones, increased vascularity of cartilage, overgrowth of cortical bone	AD	4p16.3	<i>FGFR3</i>	FGFR3	134934 <sup>a</sup> (MIM no. For FGFR3; no separate no. for SADDAN)
Small sacrosciatic notches	Multiple lucent defects metaphyses rhizomelia		AD	8p11	<i>FGFR1</i>	FGFR1	166250
Short ilia, flat acetabular roofs; unossified pubic bones	Short broad, mild/moderate metaphyseal changes, long fibulae, absent talus and calcaneus	Large, ballooned chondrocytes with matrix, growth plate hypercellular and irregular, sclerosed vascular channels	AD	12q13	<i>COL2A1</i>	Type II collagen	200610
Small ilia, flat, irregular acetabular roofs	Clublike metaphyses, delayed ossification of femoral heads, cloud effect in epiphyseal plate regions	Swiss cheese cartilage with abnormal vacuolated matrix, perilacunar foaminess, dilated RER	AD	12q13	<i>COL2A1</i>	Type II collagen	156550
Delayed ossification of pubic bones	Delayed epiphyseal ossification and deformity of hips and knees, retarded ossification of carpal and tarsal centers, coxa vara	Dilated RER in chondrocytes, microcysts in proliferative zone, columns short	AD	12q13	<i>COL2A1</i>	Type II collagen	183900

**TABLE 158-1 Clinical, Radiologic, Morphologic, and Genetic Features in the Chondrodysplasias (Associated with Defects of Growth of Tubular Bones and/or Spine)—cont'd**

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
Spondyloepime-taphyseal dysplasia, Strudwick type	Cleft palate	Pectus carinatum, scoliosis	Genu valgum	Resembles SEDC at birth	Normal	Splayed, bulbous	Early: like SEDC; later: platyspondylia, endplate irregularity, scoliosis, C1–C2 subluxation
Spondyloperipheral dysplasia	Hypoplastic midface	Short trunk, lumbar lordosis	Brachydactyly	Myopia, retinal detachment	Normal	Normal	Similar to SEDC
Arthro-ophthalmopathy (Stickler syndrome; heterogenous; also caused by defects in type IX and XI collagens)	Cleft palate, mandibular hypoplasia, midface hypoplasia		Hypotonia, hyperextension of joints, later pain and morning stiffness	Marfanoid habitus, myopia, retinal detachment, conductive hearing loss	Normal	Normal	Wedging of thoracic vertebrae and Schmorl disease
Type XI collagenopathies							
Stickler dysplasia (heterogenous)							
Otospondylo-mega-epiphyseal dysplasia (OSMED)	Cleft palate, flat face	Back pain	Short limbs, large knees and elbows, decreased joint mobility in adults	Normal stature, neurosensory deafness	Midface hypoplasia, mandibular hypoplasia	Short	Coronal clefts, platyspondylia
Weissenbacher–Zweymuller (heterozygous OSMED)	Cleft palate, flat face		Early rhizomelia, followed by catch-up growth	Normal stature, sensorineural deafness	Midface hypoplasia, mandibular hypoplasia	Short	Coronal clefts
Fibrochondrogenesis	+/- Unusual facies with hypertelorism	Narrow chest +/- omphalocele	Short +/- contractures of hands and clubbed feet	+/- Patent foramen ovale	Midface hypoplasia	Short, cupped 11 ribs	Platyspondylia, coronal clefts
Sulfation disorders group							
Achondrogenesis IB (Fraccaro)	Round face, soft skull, short neck	Short	Very short	Polyhydramnios common	Poorly ossified	Short, thin ribs, cupped ends, no fractures, no beading	Unossified vertebral bodies
Atelosteogenesis type II (including de la Chapelle dysplasia)	Unusual	Narrow, scoliosis	Short, dislocations, equinovarus, gap 1–2 digits	Cleft palate, patent foramen ovale, early death, laryngeal stenosis	Relatively normal	Short ribs	Infrequent coronal and sagittal clefting

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Delayed ischial and pubic ossification	Delayed epiphyseal ossification, peripheral ossification CFE, metaphyseal and epiphyseal changes, dappling of metaphyses with fragmentation, (fibula>tibia, ulna>radius)	Inclusion bodies in chondrocytes, hypocellular growth plates	AD	12q13	<i>COL2A1</i>	Type II collagen	184250
Delayed ischial and pubic ossification	Similar to SEDC, brachydactyly	Irregular distribution of chondrocytes, Inclusion bodies	AD	12q13	<i>COL2A1</i>	Type II collagen	271700
Normal	Mild epiphyseal dysplasia, especially CFE and distal tibiae, irregular articular surfaces, early-onset degenerative arthrosis, especially of hips		AD	12q13	<i>COL2A1</i>	Type II collagen	108300
			AD	1p21	<i>COL11A1</i>	Type XI collagen	604841
Square iliac wings	Short long bones rhizomelia, especially femora, wide prominent metaphyses; late-enlarged (mega) epiphyses		AR	6p21.3	<i>COL11A2</i>	Type XI collagen	215150
Relatively normal	Rhizomelia with dumbbell-shaped femora and humeri, resolution of bone changes		AD	6p21.3	<i>COL11A2</i>	Type XI collagen	277610
Hypoplastic	Short femora, dumbbell shaped, metaphyseal flare, very short fibulae, ectopic ossification along long bones	Densely fibrous collagenous matrix; growth plate markedly disorganized	AR	1p21.1	<i>COL11A1</i>	Type XI collagen	228520
Hypoplastic crenated ilia	Short with trapezoid femora, crenated tibiae, unossified fibulae	Matrix devoid of collagen fibrils, dense collagenous ring around cells, lack of columns, fibrous zone between resting cartilage and woven bone	AR	5q31.3–q34	<i>DTDST</i>	DTD sulfate transporter	200600
Normal sacrosclatic notch	Short dumbbell humeri (bifid distal), short dumbbell femora, enlarged 2 + 3 metacarpals, round and small middle phalanges, small fibulae	Dense collagen bundles around chondrocytes	AR	5q31.3–q34	<i>DTDST</i>	DTD sulfate transporter	256050

**TABLE 158-1 Clinical, Radiologic, Morphologic, and Genetic Features in the Chondrodysplasias (Associated with Defects of Growth of Tubular Bones and/or Spine)—cont'd**

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
Diastraphic dysplasia	Acute swelling of pinnae of ears in infancy; later, cauliflower ears	Scoliosis	Short with club feet, hitchhiker thumbs, synphalangism	Cleft palate	Ossified ear pinnae	Precocious ossification of costal cartilage	Scoliosis and lumbar interpedicular narrowing
Multiple epiphyseal dysplasia with club feet (rMED)	Normal, no cleft palate	Scoliosis	Club feet, brachydactyly				Scoliosis
Spondyloepiphyseal dysplasia, Pakistani type	Normal	Kyphoscoliosis	Bowed lower limbs, brachydactyly	Early degenerative joint disease (hands, spine)			Platyspondylia, irregular endplates
Dyssegmental dysplasia group							
Dyssegmental dysplasia, Silverman–Handmaker type	Short neck, micrognathia, hypoplastic orbits, flat facies, cleft palate	Narrow chest	Severe micromelia	Encephalocele, +/- hirsutism, patent ductus, stillborn or neonatal death	Severe midface hypoplasia, micrognathia	Very short flared ribs, round malformed scapulae	Anisodisondyly with both coronal and sagittal clefting
Dyssegmental dysplasia, Rolland–Desbuquois type	Short neck, micrognathia, hypoplastic orbits	Narrow chest	Short limbs, decreased mobility	+/- Hirsutism; +/- hemia, survival post newborn	Midface hypoplasia, mild micrognathia	Short, flared	Coronal clefting, oversized vertebrae
Filamin-related disorders							
Atelosteogenesis type I	Abnormal facies, cleft palate, micrognathia	Narrow	Severe shortening, bowing, talipes	Stillborn or neonatal death	Relatively normal	Short ribs	Platyspondylia
Atelosteogenesis type III	Midface hypoplasia, micrognathia	Narrow	Rhizomelic shortening, deviation of fingers, joint dislocations	Neural tube defect	Hypoplastic maxilla and mandible	Normal	Cervical spine: severe scoliosis/segmentation defects
Larsen syndrome	Prominent forehead, flattened face, hypertelorism, +/- cleft palate	Soft, collapsing thorax	Multiple dislocations	Severe joint laxity, +/- dysraphism of spine/neurologic impairment	Craniofacial disproportion with midface hypoplasia	Normal	Fusion defects of cervical spine
Otopalatodigital syndrome, type II	Prominent forehead, large fontanelle, midface hypoplasia, hypertelorism, micrognathia, cleft palate	Narrow chest, scoliosis	Rhizomelic shortening, dislocation of elbows and hips, camptodactyly, equinovarus deformity		Normal	Thin, posteriorly pinched	Early: slight cervical and thoracic platyspondylia

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Relatively normal	Short with broad metaphyses, delayed epiphyseal ossification, short and/or oval first metacarpals	Chondrocytes enlarged, clustered, degenerating, surrounded by dense collagen, cystic areas with fibrovascular tissue and intracartilaginous ossification	AR	5q31.3–q34	<i>DTDST</i>	DTD sulfate transporter	222600
	Multiple small epiphyses, double-layered patella, brachydactyly		AR	5q31.3–q34	<i>DTDST</i>	DTD sulfate transporter	226900
	Delayed epiphyseal ossification CFE and knees, mild metaphyseal abnormalities		AR	10q23–q24	<i>ATPSK2</i>	ATP sulfurylase/APS kinase	603005
Small round dense, amorphous ilia	Very short, broad angulated long bones, hypoplastic first metacarpals	Mucoid degeneration of cartilage, disorganized growth plate, large, unfused calcospherites	AR	1q36	<i>HSPG2</i>	Perlecan	224410
Wide flared ilia, small sacrosciatic notches	Short, broad tubular bones; dumbbell femora; enlarged first metatarsals, accelerated ossification in newborn	Resting cartilage contains patches of broad collagen fibers, growth plate normal	AR	1q36	<i>HSPG2</i>	Perlecan	224400
Small iliac wings, absent/hypoplastic ischium/pubis	Very short to absent humeri and/or femora, bowed short tibiae, absent fibulae, dyschondrocytic ossification of the hands	Acellular areas of cartilage, areas containing cell clusters and large "giant" cells	AD	3p14.3	<i>FLNB</i>	Filamin B	108720 (AO1) 112310 (Boomerang)
Vertical ischia	"Tombstone"-shaped proximal phalanges, bifid digits	Normal	AD	3p14.3	<i>FLNB</i>	Filamin B	108721
Normal	Slender, multiple joint dislocations, duplication of calcaneus		AD	3p14.3	<i>FLNB</i>	Filamin B	150250
Normal	Early bowing of the long bones, joint subluxation, carpal fusion, abnormal hypoplastic metacarpals and metatarsals, round hypoplastic phalanges	Abnormal bone	XLR	Xq28	<i>FLNA</i>	Filamin A	304120

**TABLE 158-1 Clinical, Radiologic, Morphologic, and Genetic Features in the Chondrodysplasias (Associated with Defects of Growth of Tubular Bones and/or Spine)—cont'd**

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
Osteodysplasty, Melnick–Needles	Exophthalmos, micrognathia			Malaligned teeth	Skull base sclerosis; delayed fontanelle closure	Irregular or ribbon ribs	Tall bodies, anterior–posterior concavity of bodies
Metatropic dysplasia/TRPV4 group							
Metatropic dysplasia	Normal	Tail-like sacral appendage, trunk appears long and narrow at birth, develops severe scoliosis	Short with prominent joints	Long in length at birth, appears short-limbed in infancy, short-trunked later (scoliosis)	Normal	Short, flared, cupped anteriorly	Early: markedly flattened (wafer), wide intervertebral spaces. Late: platyspondylia and scoliosis
Spondylometaphyseal dysplasia, type Kozlowski		Kyphoscoliosis, pectus carinatum	Waddling gait, knee and hip pain in childhood, limitation of large joint motion	Short trunk, short stature	Normal	Normal	Platyspondylia with open staircase appearance on AP view
Brachyolmia (AD type)		Scoliosis	Normal upper to lower segment ratios	Clinodactyly	Normal	Normal	Severe platyspondylia with flattening in cervical spine
Short rib dysplasia (SRP) (+/– polydactyly) group							
Short rib-polydactyly syndrome type I/III (Saidino–Noonan/Verma–Naumoff)	Round, flattened face	Hydropic appearance, narrow thorax, protuberant abdomen	Markedly short hands and feet, postaxial polydactyly	+/– Defects of heart, kidneys, lungs and GI tract	Normal	Very short, horizontal	+/– Flat with wide intervertebral disc spaces
Short rib-polydactyly syndrome type II (Majewski), type IV (Beemer—without polydactyly)	Short flat nose, low-set ears, cleft lip or palate	Hydropic appearance, narrow thorax, protuberant abdomen	Moderately short, pre- or +/– postaxial polydactyly	+/– PDA, dysplastic kidneys, respiratory tract anomalies; +/– OFD (1) (Mohr–Majewski)	Normal	Very short, horizontal	Relatively normal
Asphyxiating thoracic dysplasia (ATD) (Jeune)	Normal	Long narrow, prominent rosary, respiratory distress	Variable shortening, short broad hands and feet, (rare postaxial polydactyly)	Respiratory insufficiency, progressive nephropathy	Normal	Very short, cupped anteriorly	Normal
Chondroectodermal dysplasia (Ellis–van Creveld dysplasia)	+/– Midline puckering of upper lip, +/– natal teeth	Long narrow chest	Postaxial polydactyly of hands +/– of feet, acromesomelic shortening, nail dysplasia	Congenital heart disease, epispadias	Normal	Short ribs	Normal
Thoracolumbar hypoplasia (Barnes)	Normal	Narrow chest	Normal	Laryngeal stenosis	Normal	Short, horizontal orientation	Normal
Multiple epiphyseal dysplasia and pseudoachondroplasia							
Multiple epiphyseal dysplasia, types fairbanks and ribbing		Thoracic kyphosis +/– back pain	Pain and stiffness in knees hips, and ankles, waddling gait	Presents age 2 years or older	Normal	Normal	Endplate irregularity and Schmorl nodes (adult)

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Flared iliac wings, tapered ischia	Flared metaphyses of long bones; S-shaped tibiae, bowed radii, long femoral necks		XLD	Xq28	<i>FLNA</i>	Filamin A	309350
Hypoplastic crescent-shaped ilia, low-set anterior iliac spines	Short, broad club-like halberd femur	Chondrocytes vacuolated with inclusions, growth plate irregular vascularization	AD	12q24.11	<i>TRPV4</i>	TRPV4	156530
Narrow sacrosciatic notches, broad horizontal irregular acetabular roofs	Metaphyseal irregularity, hips widened epiphyseal plate, coxa vara, marked delay of carpal ossification	Proliferative zone irregular columns, fibrous appearance to matrix on EM	AD	12q24.11	<i>TRPV4</i>	TRPV4	271660
Normal	Clinodactyly		AD	12q24.11	<i>TRPV4</i>	TRPV4	113500
Small ilia, flat acetabulum	Very short, medial and lateral metaphyseal spurs, polydactyly	Disorganized growth plate, broad short trabeculae	AR	3q25	<i>IFT80</i>	IFT80	263530 263510
Normal	Short, ovoid tibiae, polydactyly, premature ossification of epiphyses	Short irregular columnization	AR	4q33	<i>NEK1</i>	NIMA-related kinase	263520 269860
Square, short ilia, flat acetabulae, spurs at margins of acetabulae	Premature ossification capital femoral epiphyses, broad proximal femoral metaphyses	Variable findings, lipid inclusions in chondrocytes, cartilage islands in metaphyses	AR	3q25 11q22.3 2q24.3	<i>IFT80</i> <i>DYNC2H1</i> <i>TTC21B</i>	IFT80 DYNC2H1 TTC21B	208500
Squared ilia with hook-like spurs at acetabulae, similar to ATD	Acromesomelic shortening with cone epiphyses, hamate-capitate fusion, slanting proximal tibial metaphyses	Variable, vascularity of cartilage, cartilage islands in metaphysis, irregular columns	AR	4p16	<i>EVC1</i> , <i>EVC2</i>	EVC protein	225500
Small pelvic outlet	Normal		AD				187760
Normal	Small irregularly ossified epiphyses involving many areas, especially hips, +/- hands and feet	Variable: normal to disturbed growth plate, inclusion bodies in chondrocytes, dilated RER	AD	6q12-14 1p33-32.2 20q13.3 2p24-23 19p13.1	<i>COL9A1</i> <i>COL9A2</i> <i>COL9A3</i> <i>MATN3</i> <i>COMP</i>	Type IX collagen Matrilin 3 COMP	120210 600204 600969 607078 132400

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
Pseudoachondroplasia	Normal skull and face	Trunk appears disproportionately long	Very short limbs with genu varum or valgum, hypermobility of joints, small broad hands	Not manifested until at least 2 years of age	Normal	Normal	Platyspondylia, anterior tongue-like protrusion, endplate irregularity
Metaphyseal dysplasias							
Metaphyseal dysplasia, type Jansen	Prominent forehead		Rhizomelic shortening, enlarged joints		Reticulate pattern in calvaria, sclerosis of base	Splayed and cupped anteriorly	Normal
Eiken dysplasia	Normal	Normal	Short limbs, brachydactyly short fibulae		Normal		Platyspondylia, delayed ossification sacrum
Blomstrand dysplasia	Unusual facies, prominent eyes, cataract, depressed nasal bridge	Narrow chest	Very short limbs	Neonatal lethal, polyhydramnios, overall increased bone density and advanced maturation	Midface hypoplasia	Thick and short	Irregular contours
Metaphyseal dysplasia, type Schmid			Waddling gait, bowed legs, generalized shortening of limbs		Normal	Normal	Irregular endplates only in early childhood
Metaphyseal dysplasia, type McKusick (cartilage-hair hypoplasia)	Fine, sparse, lightly pigmented hair and eyebrows	Harrison grooves	Short, lax ligaments, short pudgy hands, telescoping fingers	Megacolon, immune defects, propensity to skin cancer	Normal	Splayed and cupped anteriorly	Normal
Metaphyseal dysplasia with pancreatic insufficiency and cyclic neutropenia (Shwachman–Diamond)		+/- Small narrow chest	+/- Short	Pancreatic insufficiency and malabsorption, neutropenia	Normal	+/- Short, flared	Normal

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Acetabular irregularity, hypoplastic ischium and pubis	Generalized epiphyseal and metaphyseal dysplasia, hands: short tubular bones with cupped metaphyses, miniepiphyseal at CFE	Prominent inclusions in chondrocytes showing lamellar organization on EM	AD	19p13.1	<i>COMP</i>	COMP	177150
Demineralized (otherwise normal)	Metaphyses wide, splayed and frayed with cortical erosion, abnormal phalanges	Chondrocytes large, matrix fibrillar, cluster of hypertrophic cells at growth plate, irregular line of ossification with tongues of cartilage in metaphyses	AD	3p21–p22	<i>PTHrP</i>	G protein trans-membrane receptor for PTH and PTHrP	156400
Delayed ossification pubis and cap femoral epiphyses	Unusual, delayed ossification of metacarpals, metatarsals and phalanges		AR	3p21–p22	<i>PTHrP</i>	G protein trans-membrane receptor for PTH and PTHrP	600002
	All tubular bones short with wide metaphyses, +/- bowing, advanced bone maturation	Some chondrocyte vacuolization, hypertrophic and proliferative zones narrow with irregular columns	AR	3p21–p22	<i>PTHrP</i>	G protein trans-membrane receptor for PTH and PTHrP	215045
Normal	Metaphyseal splaying and cupping in many long bones (especially hips), coxa vara, normal metaphyses of hands and feet	Same as Jansen	AD	6q21–q22	<i>COL10A1</i>	Type X collagen	156500
Normal	Metaphyseal flaring and irregularity, especially knees, long distal fibulae	Same as Jansen	AR	9p21–p13	<i>RMRP</i>	RNA component of mitochondrial RNA-processing endoribonuclease	250250
Normal	Mild generalized metaphyseal irregularity	Same as Jansen	AR	7q11	<i>SBDS</i>	SBDS protein	260400

**TABLE 158-1 Clinical, Radiologic, Morphologic, and Genetic Features in the Chondrodysplasias (Associated with Defects of Growth of Tubular Bones and/or Spine)—cont'd**

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
Adenosine deaminase (ADA) deficiency		Rachitic rosary	Short	Severe combined immunodeficiency	Normal	+/- Short, cupped anteriorly	Normal
Spondyloepimetaphyseal dysplasias							
Spondyloepiphyseal dysplasia tarda (X-linked)	Normal	Sternal protrusion, back pain	Osteoarthropathy of hips and knees	Mild short trunk, short stature	Normal	Normal	Platyspondylia with hump-shaped central portion
Progressive pseudorheumatoid dysplasia		Kyphoscoliosis	Progressive arthropathy, joint stiffness/swelling		Normal	Normal	Platyspondylia, anterior endplate erosions
Dyggve–Melchior–Clausen dysplasia	Short neck	Thoracic kyphoscoliosis, scoliosis, lumbar lordosis, flared ribs, protruding sternum, short trunk	Waddling gait, enlarged joints with restriction, small claw hands	Mental retardation (most)	+/- Microcephaly	Mild flaring	Anterior pointed platyspondylia, vertebral notching
Wolcott–Rallison dysplasia	Normal	Normal	Joint pain, difficulty walking	Infantile onset diabetes mellitus, renal insufficiency, hepatosplenomegaly	Normal	Normal	Platyspondylia
Acrocapitofemoral dysplasia	Relatively large head size	Narrow thorax	Short limbs, brachydactyly			Mild metaphyseal cupping	Ovoid vertebral bodies, anterior notching
Schimke immunosseous dysplasia	Low nasal bridge, bulbous nasal tip	Short neck and trunk, hyperpigmented macules		Thyroid dysfunction, progressive renal failure, immunodeficiency, cerebral ischemia	Normal	Normal	Ovoid vertebrae
SPONASTRIME dysplasia	Prominent forehead, flat midface and nasal bridge, prognathism	Scoliosis, increased lumbar lordosis	Short limbs, joint laxity		Flattened maxilla	Normal	Lumbar vertebral changes: early: platyspondylia, child: anterior of body taller, late: vertebral body normal height
Spondyloepiphyseal dysplasia with joint laxity (SEMDJL)	Oval prominent eyes; blue sclerae; long upper lip	Kyphoscoliosis	Short limbs, spatulate nails, club foot; dislocated hips	Cleft palate; joint laxity; skin soft and doughy	Normal	Relatively normal	Kyphoscoliosis, platyspondylia, oval vertebrae

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Normal	Long bones: irregular and splayed metaphyses, spurs	Absent columns and cells; irregular calcified cartilage, poor trabecula formation	AR	20q13.11	<i>ADA</i>	Adenosine deaminase	102700
Hypoplastic iliac wings	Early: ossification delay of epiphyses, later: large epiphyses and premature osteoarthritis of hips	Fairly normal with clustering of proliferative cells	XLR	Xp22	<i>SEDL</i>	Sedlin	313400
Acetabular irregularity	Narrow joint spaces, widened metaphyses, flattened epiphyses	Clustering of chondrocytes, pyknotic nuclei	AR	6q22–q23	<i>WISP3</i>	Wnt-1 inducible signaling pathway protein 3	208230
Lacy iliac crest, hypoplastic ilia, tibiae, ischia, and acetabular roof, small sacrosciatic notches	Small epiphyses (esp. CFE), brachydactyly, cone epiphyses, small carpal centers	Foci of multiple degenerating chondrocytes surrounded by dense fibrous capsule	AR	18q12–21.1	<i>FLJ90130</i>	<i>FLJ90130</i>	223800
	Epiphyseal delay, small fragmented epiphyses, resorption of CFE	Paucity of chondrocytes; lack of columns; dilated RER; thick collagen fibers	AR	2p12	<i>EIF2AK3</i>	Eukaryotic translation initiation factor 2-alpha kinase 3	226980
Egg-shaped femoral heads, short femoral necks	Cone epiphyses, large distal femoral epiphyses, premature epimetaphyseal fusion		AR	2q35–36	<i>IHH</i>	Indian hedgehog	607778
Platyspondylia, shallow acetabular roof	Hypoplastic ilia, abnormalities, especially of CFE; occasional metaphyseal	Nests of epiphyseal chondrocytes in resting cartilage, hypocellular resting cartilage	AR	2q34–36	<i>SMARCA1</i>	SMARCA-like protein 1	242900
	Metaphyseal changes, especially distal femur, proximal tibia; striations		AR				271510
Flared iliac wings, narrow sacrosciatic notches	Epiphyseal delay; metaphyseal irregularity; radial head dislocation; short-ended tubular bones of hands and feet		AR				271640

Dysplasia	Head and Neck	Chest and Trunk	Limbs	Other	Skull	Ribs	Vertebrae
Severe spondylodysplastic dysplasias							
Achondrogenesis 1A (Houston–Harris)	Round face, soft skull, short neck	Short	Very short	Polyhydramnios common	Poorly ossified	Short thin ribs, cupped ends, fractures, beaded	Unossified vertebral bodies
Opsismodysplasia	Frontal bossing, short nose, long philtrum, abnormal ears	Narrow thorax, C1–C2 subluxation	Short stubby hands and feet	Hypotonia, susceptibility to respiratory infections	Large ossification defect	Short, severe anterior and posterior cupping	Absent; hypoplastic; platyspondylia
Spondylometaphyseal dysplasia, type Sedaghatian	Abnormal		Severe rhizomelic shortening	Neonatal lethal	Relatively normal	Occasional 11 pairs, short	Platyspondylia,
Schneckenbecken dysplasia	Large head, short neck, flat midface, +/- cleft palate	Narrow chest, distended abdomen	Very short long bones, hands and feet less severely affected	Generalized edema +/- cryptorchidism	Flat midface	Short, splayed	Platyspondylia, round anterior ossification
Spondylometaphyseal							
Spondylometaphyseal dysplasia, type corner fracture (Sutcliffe)			Waddling gait, progressive coxa vara		Normal	Normal	Increased endplate convexity, anteriorly wedged (ovoid) appearance
Brachyolmia spondylodysplasias							
Brachyolmia (Hobaek type) (Toledo type)		Short trunk, back pain in adult, mild scoliosis		Punctate corneal opacities (Toledo type)	Normal	Precocious costochondral calcification	Platyspondylia; irregular vertebral endplates, lateral extended vertebral bodies, rectangular in shape
Chondrodysplasia punctata							
Chondrodysplasia, punctata, rhizomelic type	Severe flat face, depressed bridge and tip of nose (Binder's facies)		Proximal shortening	Cataracts, ichthyosiform erythroderma, joint contractures	Midface hypoplasia	Shortened	Wide coronal clefts
Chondrodysplasia punctata, Conradi–Hünemann type	Flat face, depressed bridge and tip of nose	+/- Scoliosis	Asymmetrical shortening	Cataracts, ichthyosiform erythroderma, alopecia, joint contractures	Flat facial bones	Relatively normal	+/- Coronal clefts, marked stippling of spinal region

Pelvis	Limb Bones	Chondro-osseous Morphology	Mode of Inheritance	Chromosomal Locus	Gene	Gene Product	MIM No.
Hypoplastic crenated ilia	Short trapezoid femora, crenated tibiae, unossified fibulae	Matrix devoid of collagen fibrils, dense collagenous ring around cells, lack of columns, fibrous zone between resting cartilage and woven bone	AR	14q31	<i>TRIP11</i>	TRIP11	200600
Square iliac bones; spurs; hypoplastic ischium and pubis	Short, stocky long bones, severe metaphyseal cupping; marked epiphyseal delay; hands: short bones with metaphyseal flare	Enlarged widened hypertrophic zone with wide septae	AR				258480
"Lacy" iliac crests	Short long bones, metaphyseal cupping and irregularity, epiphyseal delay, brachydactyly	Long irregular columns	AR				250220
Snail-shaped ilia	Dumbbell-shaped femora, shortened wide fibulae, prematurely ossified tarsals	Resting cartilage hypocellular, round chondrocytes with round central nucleus, growth plate short, spicules	AR	1p31.3	<i>SLC35D1</i>	SLC35D1	269250
Normal	Developmental coxa vara, small triangular fragments originating from the metaphyses ("corner fractures")		AD				184255
Normal	Normal	Chondrocytes unevenly distributed, surrounded by dense staining material, growth plate short with clusters of hypertrophic cells	AR				271530
Trapezoid ilia, stippling of ischiopubic area	Short femora, humeri, stippled calcification in epiphyses and periarticular areas	Vascularization of cartilage with dysplastic myxoid or fibrotic areas, irregular growth plate	AR	6q22–q24 1q42 2q31	<i>PEX7</i> <i>DHAPAT</i> <i>AGPS</i>	PTS2 receptor DHAP acyltransferase AGP synthase	215100 222765 600121
Stippling of ischiopubic area	Asymmetrical shortening, stippled epiphyses in carpal and tarsal centers	Cystic myxoid degeneration of cartilage, fibrous scarring at growth plate	XLD	Xp11.2	<i>EBP</i>	Sterol-delta8-isomerase	302960

of single bones or groups of bones, which presumably do not reflect a generalized disorder of the skeleton, have been referred to as dysostoses.

Although the International Nomenclature provides a uniform standard for referring to specific disorders, so that the same disease is called the same entity by all authors, many of the names are inaccurate. For example, achondroplasia and achondrogenesis are inaccurate terms in defining the pathogenesis of these conditions, but are so well entrenched in the literature that they persist. As the morphology, pathogenesis, and especially the basic biochemical and molecular defect in each of these disorders is unraveled, this nomenclature has been updated to refer to the specific pathogenetic or metabolic defect. The etiologic or pathogenetic nomenclature is used for certain skeletal dysplasias, such as the mucopolysaccharidoses, mucopolysaccharidoses, and disorders of mineralization (e.g. b-glucuronidase deficiency, fucosidosis, hypophosphatasia).

### 158.3 CLINICAL EVALUATION

The osteochondrodysplasias are syndromes that represent generalized disorders of the skeleton and usually result in disproportionate short stature. Affected individuals usually present with the complaint of disproportionate short stature, and the abnormality in stature must first be documented by the use of the appropriate growth curves with adjustment for ethnic background and parental heights (1). In general, patients with disproportionate short stature have skeletal dysplasias, and those with relatively normal body proportions have endocrine, nutritional, prenatal, or other non-skeletal defects. There are exceptions to these rules, as congenital hypothyroidism can lead to disproportionate short stature, and a variety of skeletal dysplasias, such as osteogenesis imperfecta and hypophosphatasia, may result in normal body proportions.

A disproportionate body habitus may not be readily apparent on casual physical examination. Thus anthropometric measurements, such as upper to lower segment ratio, sitting height, and arm span, must be obtained

before the possibility of a mild skeletal dysplasia, such as hypochondroplasia or multiple epiphyseal dysplasia, can be excluded. Although sitting height is a more accurate measure of head and trunk length, it requires special equipment for consistent accuracy. Upper to lower segment ratios (U/L), on the other hand, provide a reasonably accurate measure of body proportions and can be easily obtained. The lower segment measure is taken from the symphysis pubis to the floor at the inside of the heel, and the upper segment is obtained by subtracting the lower segment value from the total height. McKusick (2) has published standard U/L curves for both white and black Americans, which are quite useful for rapid assessment of proportion (2). For example, a white infant has an upper/lower segment ratio of approximately 1.7; it reaches 1.0 at approximately 7–10 years, and then falls to an average U/L of 0.95 as an adult. Blacks, on the other hand, have relatively long limbs, and reach a U/L of approximately 0.85 as adults. Another index of limb

FIGURE 158-1

FIGURE 158-2

versus trunk length is based on the arm span measurement, which usually falls within a few centimeters of total height. These measurements are most useful in determining whether or not an abnormally short individual is proportionate or not, and the type of disproportion present. For example a short-limbed dwarf will have an abnormally high U/L ratio and an arm span that is considerably shorter than his height (Figure 158-3).

As in the differential diagnosis of most other disorders, an accurate history, family history, and physical examination may lead one to the correct diagnosis. Certain skeletal dysplasias have prenatal onset and the more severe forms are detected by fetal ultrasound and are evident at birth. However, others may not manifest until late infancy or early childhood. Thus a child who was normal until 2 years of age and then develops disproportionate short-limbed dwarfism is more likely to have pseudoachondroplasia or multiple epiphyseal dysplasia

FIGURE 158-3

than achondroplasia or spondyloepiphyseal dysplasia congenita. Furthermore, many parents may not notice short stature until 1 or 2 years of age, but, in reality, it existed from the time of birth.

A detailed physical examination may reveal the correct diagnosis or point to the likely diagnostic category (Table 158-1). First, one must establish whether the disproportionate shortening affects primarily the trunk or the limbs and, if the latter, whether it is proximal (rhizomelic), middle segment (mesomelic), or distal (acromelic), or a combination of these (Figure 158-4). The term rhizomelia is frequently inadvertently abused and should not be applied without measuring.

A variety of head and neck dysmorphisms and malformations can be seen in the skeletal dysplasias. A disproportionately large head with frontal bossing and flattening of the bridge of the nose suggests achondroplasia or thanatophoric dysplasia (TD). Cloverleaf skull is sometimes associated with TD and, rarely, with camptomelic dysplasia and a variety of malformation syndromes. Congenital cataracts suggest a form of chondrodysplasia punctata (CDP). Myopia may be found associated with any of the type II collagen disorders. Complete or partial cleft palate, bifid uvula, or high-arched palate may be found in Kniest dysplasia, spondyloepiphyseal dysplasia congenita, or diastrophic dysplasia. The upper lip is short and tethered in chondroectodermal dysplasia. Acute swelling of the pinnae of the ears occurring shortly after birth, followed by cauliflower ears, is characteristic of diastrophic dysplasia. The latter is probably one of the few truly pathognomonic findings in the skeletal dysplasias.

Postaxial polydactyly is characteristic of chondroectodermal dysplasia and of the lethal short rib-polydactyly syndromes, and may also be seen in asphyxiating thoracic dysplasia (Figure 158-5). Preaxial polydactyly is frequently observed in short rib-polydactyly syndrome II (Majewski), and, rarely, in short rib-polydactyly syndrome I (Saldino-Noonan). In diastrophic dysplasia, the hands are short and broad, the thumbs are hypermobile,

FIGURE 158-4

proximally inserted, and abducted leading to the “hitchhiker thumb” configuration, and flexion creases in the fingers are frequently absent (Figure 158-5). In achondroplastic children, the hand has a trident appearance (Figure 158-5). Hypoplastic nails are characteristic of chondroectodermal dysplasia, while the nails may be short and broad in the McKusick type of metaphyseal dysplasia (cartilage-hair hypoplasia). Shortening of the distal phalanges and second proximal phalanx is characteristic of the dysplasias named CDP, brachytelephalangic type. Club feet may be seen in infants with Kniest dysplasia, spondyloepiphyseal dysplasia congenita, and osteogenesis imperfecta, but are most characteristic of diastrophic dysplasia. Multiple joint dislocations suggest Larsen syndrome, Ehlers–Danlos syndrome type VII, or otopalatodigital syndrome; less severe degrees of joint laxity, particularly of the hands, may be seen in other types of skeletal dysplasia (e.g. cartilage-hair hypoplasia and pseudoachondroplasia). Bone fractures may occur in all of the osteogenesis imperfecta syndromes and several types of hypophosphatasia, osteopetrosis, dysosteosclerosis, and achondrogenesis type IA (Houston–Harris).

In the neonate or infant, a long, narrow thorax suggests asphyxiating thoracic dysplasia, chondroectodermal dysplasia, or metatropic dysplasia. A very small thorax is also seen in TD, the short rib-polydactyly syndromes, and homozygous achondroplasia. In some neonates with spondyloepiphyseal dysplasia congenita, the sternum and neck are short, and the chest may be small

with pectus carinatum, producing early respiratory distress. In the child or adult, scoliosis is frequently seen in metatropic dysplasia and diastrophic dysplasia.

Congenital cardiac defects are seen in several of the skeletal dysplasias. In chondroectodermal dysplasia the most common lesion is an A-V cushion defect with a common atrium. In short rib-polydactyly syndrome I (Saldino–Noonan), a variety of very complex lesions involving the great vessels, transposition or double outlet right or left ventricle, and ventricular septal defect have been reported, and in short rib-polydactyly syndrome II (Majewski) the most common cardiac defect is transposition of the great vessels.

Gastrointestinal manifestations are not common in the skeletal dysplasias, but congenital megacolon can be seen in cartilage-hair hypoplasia, malabsorption secondary to pancreatic insufficiency in the Schwachman–Diamond syndrome, and anorectal anomalies in short rib-polydactyly syndrome. Omphalocele can be a feature of otopalatodigital syndrome type II.

In the older child or adult, the complications associated with specific disorders may aid in the diagnosis. Genu varum is seen in a number of skeletal dysplasias, but in achondroplasia it is associated with lateral curvature primarily of the middle segment of the limb with overgrowth of the fibula proximally, while in cartilage-hair hypoplasia, there is generalized bowing with marked overgrowth of the fibula distally (Figure 158-6). In pseudoachondroplasia, genu varum, valgum, or a windswept abnormality may be seen, and is associated

FIGURE 158-5

FIGURE 158-6

with severe instability and ligamentous laxity at the knees (Figure 158-6). Thus, careful physical examination with delineation of all the skeletal and non-skeletal abnormalities can be quite helpful in arriving at a diagnosis.

A complete family history, including details of still-born children and parental consanguinity, should be obtained. Parents should always be closely examined, looking for evidence of a dysplasia in a partially expressed form. This is especially important in dominantly inherited disorders with wide variability of expressivity, where a parent may be mildly affected without knowing it (e.g. osteogenesis imperfecta). The appearance of a new autosomal dominant skeletal dysplasia, such as achondroplasia, is frequently associated with advanced paternal age. The health of parental sibs, especially male sibs and male relatives of the mother, should be questioned, as some conditions are inherited in an X-linked fashion. Since each of the skeletal dysplasias most frequently presents as an isolated case in the family, an isolated instance of a skeletal dysplasia in a family cannot provide information as to the mode of inheritance of the particular disorder. However, the type of familial aggregation, when it occurs, can be most helpful. For example, a pedigree with affected sibs and normal parents suggests a recessive type of disease and argues against autosomal dominant disorders, such as achondroplasia and hypochondroplasia. However, germ cell mosaicism can also account for this situation, as in osteogenesis imperfecta II and pseudoachondroplasia, and this phenomenon may be much more common than previously appreciated. If two achondroplastic parents produce a severely affected offspring, it is most likely homozygous achondroplasia, rather than TD. However, different modes of inheritance have been observed in disorders that are difficult to distinguish clinically, such as the autosomal dominant and recessive forms of multiple epiphyseal dysplasia and osteogenesis imperfecta type 3.

#### 158.4 RADIOLOGIC EVALUATION

The next step in the evaluation of the disproportionately short patient is to obtain a full set of skeletal radiographs. A full series of skeletal views, including anteroposterior (AP) and lateral views of the skull, AP and lateral views

of the spine, and AP views of the pelvis and extremities, with separate views of the hands and feet, is optimal. A lateral radiograph of the knees can be helpful in diagnosing the recessive form of multiple epiphyseal dysplasia (MED). Lateral views of the foot are particularly helpful in identifying punctate calcification of the calcaneus, which may be a clue to the diagnosis of the milder forms of CDP, in confirming the absence or hypoplasia of the calcaneus and talus in newborns with spondyloepiphyseal dysplasia congenita, or in delineating the double ossification centers of the calcaneus in Larsen syndrome and asphyxiating thoracic dystrophy. However, owing to their intrinsic natural variability, radiographs of the feet are not generally helpful. An abridged skeletal survey should include at a minimum AP view of the pelvis and AP views of the knees, left hand, and lateral spine. Skeletal radiographs alone are often sufficient to make an accurate diagnosis, since the classification of skeletal dysplasias has been based primarily on radiographic criteria (Table 158-1). Attention should be paid to the specific parts of the skeleton involved (spine, limbs, pelvis, skull), and within each bone, to the location of the lesion (epiphysis, metaphysis, diaphysis) (Figures 158-1 and 158-2). The skeletal radiographic features of many of these diseases change with age, and it is usually beneficial to review radiographs taken at different ages when possible. In some disorders, the radiographic abnormalities following epiphyseal plate fusion are nonspecific, so that the accurate diagnosis of an adult disproportionate dwarf may be impossible unless prepubertal films are available.

Radiologic diagnosis is also based upon recognition of unique patterns of abnormal skeletal ossification, such as the total lack or marked reduction of ossification of the vertebral bodies in the achondrogenesis syndromes (Figure 158-7). Some radiographic features characterize certain disorders. For example in achondroplasia the acetabulae are flat with tiny sacrosciatic notches, rather square iliac wings with rounded corners, and an oval translucent area in the proximal femora and humeri in infants. The finding of a decreasing interpediculate distance from L1 to L5 is seen nearly uniformly in people with achondroplasia and hypochondroplasia. In Kniest dysplasia and metatropic dysplasia, the long

FIGURE 158-7

bones, and femora in particular, have a dumbbell-shaped appearance in the newborn period. Bowing of the limbs (camptomelia) is observed in camptomelic dysplasia, osteogenesis imperfecta, congenital hypophosphatasia, TD, and a heterogeneous group of disorders with broad, bent long bones.

There are calcified projections or spikes on the medial borders of the metaphyses of the femora in TD, and medial and lateral borders in short rib-polydactyly syndrome I/III (Figure 158-7). Cupping of the ends of the ribs and the long bones and metaphyseal flaring are features of a large number of dysplasias, including achondroplasia, the metaphyseal dysplasias, asphyxiating thoracic dysplasia, and chondroectodermal dysplasia.

While fractures in the newborn suggest one of the osteogenesis imperfecta syndromes, they may also be seen in congenital osteopetrosis and severe hypophosphatasia. In achondrogenesis type IA (Houston–Harris), the ribs are thin and wavy with beading, suggesting fractures, but the long-bone and vertebral findings readily distinguish this dysplasia from osteogenesis imperfecta. In the older individual, fractures may also be seen in a variety of osteopetrotic syndromes, including dysosteosclerosis and pyknodysostosis.

Retarded ossification manifest by absence of epiphyseal centers or marked delay in their ossification, is found in the various forms of type II collagen disorders and other spondyloepimetaphyseal and multiple epiphyseal dysplasias. Although less common, advanced carpal ossification is seen in certain skeletal dysplasias, such as Desbuquois syndrome. Stippling of the epiphyses is characteristic of the various forms of CDP, but may also be seen with Zellweger syndrome, warfarin-related embryopathy, and occasionally, lysosomal storage diseases, Smith–Lemli–Opitz syndrome, and congenital infections.

Rib shortening is most severe in the short rib-polydactyly syndromes and TD, but may also be marked in patients with asphyxiating thoracic dysplasia, chondroectodermal dysplasia, and metatropic dysplasia. It is also quite marked in children with compound skeletal dysplasias like homozygous achondroplasia.

Marked decrease in or absence of ossification of the vertebral bodies suggests a diagnosis of achondrogenesis (Figure 158-7). Deficient ossification of several vertebral bodies with good preservation of the pedicles is fairly specific for hypophosphatasia. Marked reduction in ossification of the cervical, upper thoracic, and lower lumbosacral vertebral bodies may also be seen in spondyloepiphyseal dysplasia congenita, Kniest dysplasia, and other types of spondyloepiphyseal dysplasias. Severe platyspondylia is characteristic of metatropic dysplasia, lethal perinatal osteogenesis imperfecta type II, TD, Morquio disease, and spondylometaphyseal dysplasia (Kozlowski type), among others. In TD, the vertebrae have a characteristic ossification defect so that they appear U-shaped (pedicles taller than vertebral bodies) in the thoracic spine, but with an H and inverted U shape

in the lumbar spine (Figure 158-7). In spondylometaphyseal dysplasia (Kozlowski type), the AP view of the spine is characteristic, with a central core and widened platyspondylic bodies that overhang the overfaced pedicles, reminiscent of an open staircase. Similar overfaced pedicles are seen in brachyolmia and metatropic dysplasia. Coronal clefts of the vertebrae can be seen in Kniest dysplasia, dyssegmental dysplasia Rolland–Desbuquois type, Weissenbacher–Zweymüller syndrome, atelosteogenesis, short rib-polydactyly syndrome type I, and various types of CDP.

These examples are representative of but a few of the many typical radiographic features seen in the skeletal dysplasias (Table 158-1). In many instances, an accurate diagnosis can be made by simply examining the skeletal radiographs, but in other disorders only the general type of dysplasia, such as spondyloepiphyseal dysplasia, can be readily classified, and further information may be required to diagnose its exact form. Furthermore, only part of the heterogeneity of the skeletal dysplasias has been delineated to date and there are many disorders that will require morphologic, biochemical, or molecular studies for their exact delineation.

## 158.5 CHONDRO-OSSEOUS MORPHOLOGY

Morphologic studies of chondro-osseous tissue have revealed specific abnormalities in many of the skeletal dysplasias (3–7) (Table 158-1). In certain of these disorders, histologic examination of chondro-osseous tissue may be useful in making an accurate diagnosis of the specific skeletal disorder. In other disorders, no histopathologic alterations are present, or they are nonspecific, and in these cases pathologic examination is useful only in ruling out a diagnosis.

On morphologic grounds, the chondrodysplasias can be broadly divided into those disorders (1) that show no qualitative abnormality in endochondral ossification, (2) in which there are abnormalities in cellular morphology, (3) that have abnormalities in matrix morphology, and (4) in which the abnormality is primarily localized to the area of chondro-osseous transformation. In certain disorders, abnormalities in two or more of these areas can be seen.

Conditions with minimal disturbance of endochondral ossification include achondroplasia and hypochondroplasia, where endochondral ossification is qualitatively normal, but where there are some abnormalities in the height and arrangement of proliferative columns, particularly in the center of the large growth plates. In asphyxiating thoracic dysplasia, where several workers have shown prominent lipid inclusions in chondrocytes, the growth plate organization is essentially normal, but calcified cartilage cores are seen far into the metaphysis.

In the achondrogenesis syndromes, defects in cellular morphology, matrix, and/or chondro-osseous

transformation can be seen. In achondrogenesis 1A (Houston–Harris) the chondrocytes are large and contain prominent periodic acid-Schiff (PAS)-positive inclusions. Endochondral ossification is markedly disturbed with absence of columns of proliferative cells and lack of cellular hypertrophy. In achondrogenesis II (Langer–Saldino) there is complete disruption of endochondral ossification with large chondrocytic lacunae and little intervening matrix (Figure 158-8).

In TD (Figure 158-8), and short rib-polydactyly type I and type II, there appears to be defective maturation of chondrocytes with reduced and disorganized columnization. Consequently, vascular invasion and chondro-osseous trabeculae are short and deformed with bridging between the trabeculae. Hypertrophic chondrocytes are irregularly arranged at the zone of chondro-osseous transformation and lack columnization. Bands of mesenchyme-like fibrous tissue extend from the perichondrial area into the growth plate. Periosteal bone extends up over the cartilage peripherally.

A group of conditions show dilatation of the chondrocyte rough endoplasmic reticulum (RER), consistent with defective synthesis or abnormal processing of matrix proteins that accumulate in the RER. These include pseudoachondroplasia, where the inclusions are prominent and in some cases show a highly regular RER inclusion (Figure 158-8), consisting of alternating electron-dense and electron-lucent lamellae reflecting the accumulation of cartilage oligomeric matrix protein (COMP) and other structural components of the cartilage extracellular matrix. Dilatation of the RER is seen also in spondyloepiphyseal dysplasia, spondylometaphyseal dysplasia (Kozlowski), some forms of multiple epiphyseal dysplasia, and Kniest dysplasia, among others. Thus dilatation of the RER is not a diagnostic finding, but identification of the accumulated material will lead to the biochemical and molecular basis of the disorder.

The matrix pathology in Kniest dysplasia is striking. Endochondral cartilage with paraffin processing shows dehiscence of matrix leading to the Swiss cheese cartilage appearance. With plastic embedding, these are areas of relatively acellular matrix surrounded by attenuated chondrocytes with a bubbly appearance to the perilacunar matrix.

Matrix abnormalities are also seen in diastrophic dysplasia, CDP (various types) and the Dyggve–Melchior–Clausen syndrome. In diastrophic dysplasia, the matrix of the reserve zone cartilage develops a particularly fibrillar appearance and shows areas of microscar formation (Figure 158-8). Chondrocytes, both by light microscopy and by electron microscopy, are surrounded by dense corona of large collagen fibers. The observation of similar perichondrocytic rings in atelosteogenesis II and achondrogenesis IB led to the successful search for a common pathogenetic mechanism in these three disorders; that is, mutations in the diastrophic dysplasia sulfate transporter gene. In Dyggve–Melchior–Clausen syndrome, chondrocytes by light microscopy appear to be arranged around a relatively large common lacuna, with up to 10 chondrocytes clustered around each lacuna. In CDP of both the rhizomelic recessive and X-linked dominant Conradi–Hunermann varieties, there appears to be an alteration in epiphyseal and reserve zone cartilage matrix with areas of dystrophic (nonendochondral) ossification, fibrous dysplasia, and even areas of fat deposition.

Syndromes with striking histopathologic abnormalities have been reported by Stanescu et al. (6), (fibrochondrogenesis) and Greenberg et al. (8). Achondrogenesis IA (Houston–Harris) and IB (Fraccaro) have been distinguished one from the other by morphologic as well as radiographic differences (9,10); however, achondrogenesis type II (Langer–Saldino) and hypochondrogenesis

FIGURE 158-8

have identical chondro-osseous morphology and represent variability in a single disorder (type II collagen disorders). Thus pathologic analysis of chondro-osseous tissue can be of great help in the diagnostic evaluation of the chondrodysplasias, in the delineation of new syndromes, and the lumping of related disorders.

## 158.5 BIOCHEMICAL AND MOLECULAR ABNORMALITIES

Based on similarities in clinical, radiographic, and morphologic features, the chondrodysplasias have been grouped into bone dysplasia families, which Spranger had hypothesized share common pathophysiologic mechanisms. In recent years, the great progress that has been made in our knowledge of the basic biology of skeletogeny, and the advances of the human genome initiative have resulted in an explosion of knowledge concerning the biochemical and molecular defects in the skeletal dysplasias. Through various methods, including the candidate gene approach, positional cloning, human–mouse synteny, and whole-exome sequencing, specific gene defects that produce the skeletal dysplasias have been identified. These may be classified into several general categories, which are designed to reflect the pathogenesis of the disorders: (1) defects in extracellular structural proteins, (2) defects in metabolic pathways (including enzymes, ion channels, and transporters), (3) defects in folding and degradation of macromolecules, (4) defects in hormones and signal transduction mechanisms, (5) defects in nuclear proteins and transcription factors, (6) defects in oncogenes and tumor suppressor genes, (7) defects in RNA and DNA processing and metabolism, and (8) defects in intracellular structural proteins (11,12). There remain many dysplasias whose underlying molecular mechanism has yet to be discovered and may require the addition of new categories. The following are examples of each group but do not represent a complete listing in each category.

### 158.5.1 Defects in Extracellular Structural Proteins

**158.5.1.1 Type II, IX, and XI Collagens.** Since type II collagen is found primarily in cartilage, the nucleus pulposus, and the vitreous of the humor of the eye, it was postulated that type II collagen defects would be found in those disorders in which these specific tissues are affected (13,14). Indeed, biochemical and molecular defects in type II collagen have now been found in a large group of patients with phenotypes ranging from the lethal achondrogenesis II and hypochondrogenesis, to the various spondyloepiphyseal dysplasias and spondyloepimetaphyseal dysplasias (SEMD), through Kniest dysplasia, Stickler syndrome, and mild spondyloepiphyseal dysplasia, resulting in “precocious” familial osteoarthropathy (10,11). These

disorders can be grouped together under the term “type II collagenopathies” and run a continuous phenotypic spectrum. They have in common heterozygous mutations of the type II collagen gene (*COL2A1*). The majority of these patients also have electrophoretically detectable abnormalities in cartilage type II collagen. There appears to be a direct correlation between the ratio of type I to type II collagen in cartilage and the clinical severity of the disorder. Normally, type I collagen is not found in cartilage; however, in achondrogenesis type II, which is the most severe of these disorders, only type I collagen is seen in cartilage. In hypochondrogenesis, which is less severe radiographically, cartilage contains both type I collagen and post-translationally overmodified type II collagen. In the spondyloepiphyseal dysplasias, type I collagen is not seen at all, and both overmodified and normal type II collagen can be found in cartilage.

Mutations that result in a substitution for a triple helical glycine residue appear to be the most common type of mutation (11). In most cases of achondrogenesis II/hypochondrogenesis in which mutations have been defined, there are nucleotide substitutions for a glycine residue, which are clustered toward the carboxy-terminal end of the molecule. In a few cases, small deletions or splice site mutations have been found in achondrogenesis II/hypochondrogenesis (15). In the spondyloepiphyseal and SEMD, a variety of single nucleotide substitutions have been described throughout the molecule, in addition to deletions and insertions. Kniest dysplasia appears to be somewhat unique in having splice junction mutations clustered around the amino-terminal end of the molecule (16,17). Interestingly, a variant with brachydactyly (spondyloperipheral dysplasia) is associated with truncating mutations in the c-propeptide domain of *COL2A1* (18,19).

Stickler syndrome is genetically heterogeneous, with mutations described in *COL2A1*, *COL9A1*, *COL9A2*, and *COL11A1*, and there is a non-ocular form with mutations in *COL11A2*. Approximately half the patients have been found to have mutations in type II collagen, and all have resulted in premature termination of translation, presumably leading to decreased synthesis of type II collagen (20). Mutations that result in the synthesis of qualitatively abnormal type II collagen chains lead to more severe phenotypes, and mutations that result in reduced synthesis of structurally normal type II collagen produce the milder Stickler phenotype.

Type XI collagen is a heterotrimer composed of three distinct alpha chains encoded by *COL11A1*, *COL11A2*, and *COL2A1*. In Stickler syndrome, the majority of the mutations reported in *COL11A1* result in premature end of translation (21). It appears that those patients with *COL11A1* mutations have more severe and earlier hearing loss as well as a different vitreous phenotype, as compared with those patients with a *COL2A1* mutation. A variety of mutations have now been described in *COL11A2* in other cases of Stickler syndrome (22).

These appear to be distinct from the other Stickler cases, in that they do not have the severe myopia and vitreoretinal degeneration, consistent with the fact that *COL11A2* is not expressed in the vitreous humor.

OSMED (otospondylomegapeiphyseal dysplasia) is an autosomal recessive skeletal dysplasia caused by loss-of-function mutations in *COL11A2* (23). It has many similarities to the type II collagenopathies, particularly Kniest and Stickler syndromes, but is associated with profound sensorineural hearing loss and lack of ocular involvement. Another phenotype, referred to as Weissenbacher–Zweymüller syndrome or heterozygous OSMED, is essentially a form of non-ocular Stickler syndrome with skeletal radiographic findings that resolve with age. It is caused by a heterozygous glycine substitution in *COL11A2* (24). Mutations in *COL11A1* have also been described in fibrochondrogenesis.

Type IX collagen is a heterotrimeric nonfibrillar collagen composed of three  $\alpha$  chains encoded by three distinct genes: *COL9A1*, *COL9A2* and *COL9A3*. Some families with multiple epiphyseal dysplasia have specific splice site mutations predicted to cause exon skipping, which would interfere with one of the collagenous domains of type IX collagen and thus disturb its interaction with other matrix proteins. This type of mutation, and only this type, has been described for *COL9A1* (25), *COL9A2* (26,27), and *COL9A3* (28). The patients with multiple epiphyseal dysplasia (MED) due to type IX collagen gene mutations tend to have severe changes at the knees and relative hip sparing. A *COL9A2* allele causing a tryptophan substitution for a glutamine residue within the second collagenous domain of  $\alpha 2(\text{IX})$  has been associated with intervertebral disc disease in a few Finnish families (29). Homozygous loss-of-function mutations leading to Stickler syndrome phenotype have been described for *COL9A1* and *COL9A2* (30,31). This is perhaps not surprising given the overlap in expression patterns with *COL2A1* and type X1 collagen genes. Of note though, neither the heterozygous carriers of the loss-of-function mutations nor the homozygotes suffer from MED, clearly indicating that the MED-associated mutations are acting via a dominant negative mechanism.

**158.5.1.2 Type X Collagen.** Mutations in *COL10A1* have been defined in the Schmid type of metaphyseal chondrodysplasia (32,33) and presumably lead to a reduced amount of type X collagen in the matrix. This correlates with the presence of type X collagen exclusively in the hypertrophic zone of the growth plate. All the mutations appear to map to the same region of the gene, which encodes the carboxypropeptide required for triple helical formation. Other forms of metaphyseal dysplasia, however, do not have mutations in this molecule.

**158.5.1.3 Cartilage Oligomeric Matrix Protein.** Cartilage oligomeric matrix protein (COMP) is coded for by a gene on the short arm of chromosome 19 where the pseudoachondroplasia phenotype had been mapped. A variety of mutations have now been defined in the *COMP*

gene in cases of pseudoachondroplasia, as well as in a number of cases of MED (34,35). COMP is a member of the thrombospondin family of extracellular calcium-binding proteins, and the majority of mutations occur in the calmodulin-like repeat regions of the molecule, with a minority found in the globular carboxyl-terminal region (36). Some MED patients also have mutations in the gene for another cartilaginous structural protein, matrilin 3 (37,38), thus there are at least six different causative genes for MED (*COMP*, *COL9A1*, *COL9A2*, *COL9A3*, *MATN3* and *DTDST*) making this relatively mild skeletal dysplasia one of the most genetically heterogeneous.

## 158.5.2 Defects in Metabolic Pathways

### 158.5.2.1 Diastrophic Dysplasia Sulfate Transporter.

Diastrophic dysplasia was mapped to chromosome 5q by linkage disequilibrium mapping. Hästbacka et al. (39), identified a gene that closely resembled a sulfate transporter gene previously described in the rat. Reduced sulfate transport appears to have a dramatic effect on sulfation of chondroitin sulfate-containing proteoglycans, a family of highly expressed and heavily sulfated proteins that participate in the function of cartilage in supporting compressive loads. Although diastrophic dysplasia sulfate transporter (*DTDST*) is also expressed in other tissues, cartilage is hypothesized to be disproportionately affected because of the cartilage's high demand for sulfate and its avascular nature. A number of mutations in the *DTDST* gene have been described in both Finnish and non-Finnish patients with this disorder (39).

Superti-Furga et al. (40) described similar defects in sulfate uptake in cartilage from patients with the more severe disorder known as achondrogenesis 1B. Based on the similar morphologic characteristics of cartilage in these three disorders (i.e. rings of collagen around the chondrocytes), mutations in *DTDST* were sought in atelosteogenesis type II, and eventually identified. Most mutations are located within the coding region of the *DTDST* gene. There appears to be some genotype–phenotype correlation with the most severe disease—achondrogenesis 1B—due to homozygosity or compound heterozygosity for mutations resulting in a null phenotype or amino acid substitutions in the transmembrane domains. When one of these mutations is paired with a mutation having a less dramatic effect, e.g. an amino acid substitution within a cytoplasmic domain, the phenotype is less severe; i.e. either atelosteogenesis II or diastrophic dysplasia (41). The allele R279W, first reported in atelosteogenesis type II, has been shown to cause a recessive type of multiple epiphyseal dysplasia when homozygous. This form of MED shows the clinical features of brachydactyly and club foot and the interesting radiographic feature of double/multi-layer patella on lateral knee radiographs (42).

**158.5.2.2 Arylsulfatase E.** The X-linked recessive form of CDP was mapped to the short arm of the X

chromosome (Xp22.3), near the boundary of the pseudoautosomal region close to the steroid sulfatase locus. Franco et al. (43) identified three adjacent genes that encoded previously unrecognized sulfate enzymes in this region of the chromosome, which were named arylsulfatase (ARS) D, E, and F. Missense mutations in the *ARSE* gene were found in a number of male patients with CDP and in several male patients given the diagnosis of brachytelephalangic CDP. Subsequently nonsense mutations and large deletions have been reported in multiple patients with brachytelephalangic CDP (44).

**158.5.2.3 Sterol Biosynthesis.** Smith–Lemli–Opitz syndrome (SLOS) is a multiple congenital anomaly syndrome characterized by the accumulation of 7-dehydrocholesterol due to deficiency in 7-dehydrocholesterol reductase, the final step in the enzymatic synthesis of cholesterol. A small minority of patients with SLOS have stippled epiphyses. This suggested that blocks in other steps of the cholesterol biosynthesis pathway might be responsible for some forms of CDP. Investigations subsequently showed that patients with Conradi–Hunermann CDP had increased levels of 8-dehydrocholesterol and cholest-8(9)-en3bol, which suggested that the enzyme delta(8)-delta(7)-sterol isomerase was deficient. Mutations have now been found in the gene for this enzyme in several patients (45,46). Abnormal sterol elevations have also been detected in patients with hydrops-ectopic calcification-moth-eaten bones (HEM) skeletal dysplasia. Subsequently, mutations have been identified in the lamin B receptor (*LBR*) gene (47) which is now recognized as the primary sterol delta(14)-reductase, with heterozygotes having the Pelger–Huet anomaly in granulocytes as their only clinical sign (48).

### 158.5.3 Defects in Folding and Degradation of Macromolecules

**158.5.3.1 Other Lysosomal Enzyme Defects.** Mutations in a large number of genes coding a variety of lysosomal enzymes have been described in the mucopolysaccharidoses and mucopolipidoses (see Chapter 102). There is a great degree of variability in the severity of the skeletal changes, but they fall under the general heading of dysostosis multiplex (beaking of lumbar vertebrae, proximal pointing of metacarpals, J-shaped sella turcica, paddle ribs, acetabular changes) (49).

### 158.5.4 Defects in Hormones and Signal Transduction Mechanisms

**158.5.4.1 Fibroblast Growth Factor Receptor 3.** In 1994, the achondroplasia gene was mapped to the short arm of chromosome 4 (4p16.3) close to the Huntington disease locus (9,50). During the long search for the Huntington disease gene, a potential candidate for achondroplasia was identified; that is, fibroblast growth factor receptor 3 (*FGFR3*). Within a few months of the

linkage report, mutations in *FGFR3* were found to be responsible for achondroplasia (51). Of great interest was the finding that over 98% of the cases analyzed were due to the same amino acid substitution (Gly380Arg). Almost all of the cases carry the same mutation, a G to A transition at nucleotide 1138, and the remaining cases had a G to C transversion at the same nucleotide, resulting in the same amino acid substitution. Since over 80% of cases of achondroplasia represent new mutations, this represents the single most common mutation known in man.

A number of mutations in *FGFR3* have now been found in TD (52). Individuals who have thanatophoric dysplasia type II (TDII), with straight femora and severe cloverleaf skull, all had mutations on codon 650, causing a lysine to glutamic acid substitution in the intracellular TK domain. Severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN) is a rare form of achondroplasia which is also due to a mutation at codon 650 (lysine to methionine) (53). SADDAN is often compatible with survival to adulthood, and lacks the cloverleaf skull seen in TDII.

In cases of thanatophoric dysplasia type I (TDI) with curved femora, with or without cloverleaf skull, most of the mutations have been found in the extracellular domain and have in common a substitution of a cysteine for another amino acid; for example, arg248cys, ser249cys, ser371cys, tyr373cys. The French group has also described mutations in a stop codon (807) in five patients with TDI (54).

Heterozygosity for *FGFR3* mutations has also been detected in hypochondroplasia. A lysine to asparagine substitution at codon 540 accounts for roughly 50% of hypochondroplasia (55,56). A few patients have been found to have different substitutions in *FGFR3*, and many cases of hypochondroplasia are apparently unlinked to *FGFR3*.

**158.5.4.2 Parathyroid Hormone-Related Peptide Receptor.** Jansen-type metaphyseal chondrodysplasia is an autosomal dominant skeletal dysplasia with rickets-like changes in the metaphyseal areas of the bones. Schipani et al. (57) defined a mutation in the parathyroid hormone (PTH)/parathyroid hormone-related peptide (PTHrP) receptor (*PTHrP1*) (57). The heterozygous mutation caused a histidine to arginine substitution at position 223 in the PTHrP receptor protein. This mutation has now been found in several patients with Jansen metaphyseal dysplasia and a few other mutations have also been identified (58). These mutations lead to constitutive ligand-independent activation of the PTH/PTHrP receptor and consequently hypercalcemia, hypophosphatemia, and the radiographic abnormalities.

Blomstrand dysplasia is a lethal chondrodysplasia characterized by sclerosis and advanced endochondral ossification; that is, the radiographic abnormalities are the opposite of those seen in Jansen metaphyseal dysplasia. Recently, mutations resulting in absence of

functional PTH/PTHrP receptors have been identified in patients with Blomstrand dysplasia (59). A second recessive skeletal dysplasia, Eiken syndrome, has been shown to result from truncating mutations in the C-terminal cytoplasmic tail (60). This rare dysplasia has severely retarded epiphyseal ossification and long-bone changes that are somewhat similar to Jansen-type metaphyseal dysplasia (61).

### 158.5.5 Defects in Nuclear Proteins and Transcription Factors

**158.5.5.1 SOX9.** Camptomelic dysplasia of the classic long-bone variety is one of the few disorders associated with sex reversal. A substantial number of XY individuals have genital abnormalities that range from minor abnormalities of the external genitalia to complete sex reversal. Chromosomal rearrangements in cases of camptomelic dysplasia localized the gene responsible to 17q24.1–q25.1. High-resolution mapping of the candidate region positioned a breakpoint in one patient close to the *SOX9* locus. *SOX9* is a transcription factor gene structurally related to the *SRY* (sex-determining region Y gene), which encodes the factor necessary for testicular development in mammals (62) and cartilage development (63). Dosage of this transcription factor is critically important for normal development. Mutations of *SOX9* leading to haploinsufficiency have now been reported in a number of patients with classic camptomelic dysplasia who are chromosomally normal, including 46,XX and 46,XY females, as well as a 46,XX male (63,64). Several patients with camptomelic dysplasia due to chromosomal rearrangements have breakpoints outside the coding region of the gene (65) indicating that disruption of the control region is sufficient to produce the camptomelic phenotype. All of the mutations to date have been heterozygous, negating the previously proposed autosomal recessive inheritance of this disorder. Thus, camptomelic dysplasia of the classic type is an autosomal dominant trait, and intergenerational transmission has been documented (66). The gene is expressed in condensing mesenchyme, but not in mature chondro-osseous tissue. Genomic changes in the regions surrounding the *SOX9* locus can cause milder phenotypes, including isolated Pierre–Robin sequence and the brachydactyly-anonychia syndrome (67).

**158.5.5.2 SHOX.** Dyschondrosteosis was mapped to the short arm of the X chromosome following the observations of XY translocations in some patients with Leri–Weill dyschondrosteosis and the occurrence of a Madelung deformity in some Turner syndrome patients. The short stature homeobox-containing gene (*SHOX*) maps to the pseudoautosomal region of Xp and encodes a homeodomain-containing transcription factor. This gene escapes X-inactivation. Several mutations causing haploinsufficiency of *SHOX* (nonsense mutations and deletions) have been found in patients with

dyschondrosteosis, and those patients with homozygous mutations or deletions have the more severe phenotype of Langer mesomelia (68,69).

### 158.5.6 Defects in Oncogenes and Tumor Suppressor Genes

**158.5.6.1 Multiple Exostoses, Trichorhinophalangeal Syndromes.** Hereditary exostoses (EXT) is an autosomal dominant disorder that has been shown to be heterogenous on molecular grounds. *EXT1* on 8q and *EXT2* on 11p have both been cloned, and mutations in these genes account for approximately 70% of patients with multiple exostoses. There is a third locus at 19p. The Langer–Giedion syndrome is a contiguous gene disorder caused by a microdeletion on chromosome 8 with features of the trichorhinophalangeal syndrome (sparse hair, bulbous nose, short stature) and multiple exostoses. Haploinsufficiency for the transcription factor *TRPS1* is responsible for the trichorhinophalangeal phenotype (70) and haploinsufficiency for *EXT1* is responsible for the multiple exostoses phenotype.

### 158.5.7 Defects in RNA and DNA Processing and Metabolism

**158.5.7.1 Cartilage-Hair-Hypoplasia.** Cartilage-hair-hypoplasia (CHH) is an autosomal recessive condition more prevalent among the Amish and the Finnish. Radiographically, it is a metaphyseal dysplasia with brachydactyly. The pleiotropy of this disorder is often emphasized, with manifestations ranging from sparse hair to aganglionic megacolon to immune deficiency. However, variability is huge and even a skeletal-only form exists (71). Mutations in the gene *RMRP* have been reported in patients of various ethnicities. The gene product is not a protein but rather a functional RNA, which forms part of a complex dedicated to cleavage of RNA in mitochondrial DNA synthesis and processing of pre-rRNA (72).

**158.5.7.2 Shwachman–Diamond Syndrome.** Shwachman–Diamond syndrome shares cardinal features with CHH: recessively inherited metaphyseal dysplasia with immune deficiency. It has the additional feature of pancreatic insufficiency, which can be helpful in arriving at the diagnosis (73). The dysplasia is caused by mutations in the *SBDS* gene (74), which is transcribed to protein, but like the *RMRP* product, is involved in RNA metabolism (75).

### 158.5.8 Defects in Intracellular Structural Proteins

**158.5.8.1 Filamin-A-Related Disorders.** Filamin A is an actin-binding protein which forms an integral part of the cytoskeleton. Loss-of-function mutations in the X-linked gene coding for this protein were originally described in girls with periventricular nodular

heterotopias who did not have any skeletal phenotype. It came as a surprise when, several years later, gain-of-function or altered-function mutations were described in the same gene in the otopalatodigital (OPD) family of disorders: OPDI, OPDII, Melnick–Needles syndrome, and frontometaphyseal dysplasia (76). There is considerable variability in severity in this group but also enough similarity to allow their grouping prior to molecular proof. These skeletal phenotypes did not have an associated neurologic component. However, in 2004, one patient has been described with features of both forms of filamin-A-related disorders. A girl with a single missense mutation (L2439M) had both bilateral periventricular nodular heterotopias and frontometaphyseal dysplasia (77), indicating that the phenotypes are not always so separate.

**158.5.8.2 Filamin-B-Related Disorders.** Filamin B is structurally similar to filamin A and probably has a similar role within the cellular cytoskeleton. Mutations were identified in a spectrum of skeletal dysplasias with predominant spine and articular involvement (78). Recessive loss-of-function mutations were found in families with spondylcarpotarsal syndrome (a phenotype characterized by vertebral, carpal, and tarsal fusions) whereas dominant missense mutations were identified in individuals with Larsen syndrome, atelosteogenesis I, and atelosteogenesis III (78). This confirmed the clinical impression that atelosteogenesis III and Larsen syndrome were allelic but also demonstrated once more that apparently unrelated conditions such as spondylcarpotarsal and atelosteogenesis could arise from different mutation effects on the same protein, as had been seen with filamin A.

## 158.6 SUMMARY

In addition to clinical and radiographic tools, the evaluation of skeletal dysplasias often requires morphologic, biochemical, and molecular investigations. Diagnosis of the specific form of skeletal dysplasia can be of great importance in the prognosis, prevention, and treatment of these disorders, and in the provision of accurate genetic counseling. Since space constraints prevent independent discussion of each of the many chondrodysplasias in this chapter, a few of the extremely rare disorders have been left out and for the majority, the salient clinical, radiographic, pathologic, and genetic characteristics are outlined in Table 158-1. The reader is referred to the classified Further Reading at the end of this chapter for further details concerning each of these syndromes.

## Biographies

**Dr Sheila Unger** is a Canadian-born geneticist with a longstanding interest in the skeletal dysplasias. She completed her medical genetics training at the University of Toronto and then did a 2-year fellowship with Professor Dan Cohn at UCLA in conjunction with the International Skeletal Dysplasia Registry at Cedars-Sinai hospital. She currently lives and works in Lausanne, Switzerland, and serves as the clinical and radiographic coordinator for the European Skeletal Dysplasia Network (ESDN). She is a founding member of the International Skeletal Dysplasia Society.

**Dr Ralph S Lachman, MD**, completed his pediatric residency at the Mount Sinai Hospital and served in the US Army as base pediatrician in Bad Kreuznach, Germany. The next 4 years were occupied with a diagnostic radiology residency at the New Mount Sinai Hospital. This was followed by a pediatric radiology fellowship at Harvard's, Boston Children's Hospital. He is boarded in both diagnostic radiology and pediatrics. He is also "Subspecialty boarded" in pediatric radiology, for which he was one of the original candidates. He became the first pediatric radiologist at Harbor-UCLA Medical Center, joining the faculty of medicine at UCLA. Another fateful event occurred in 1970, the simultaneous arrival of Dr Lachman and Dr David L Rimoin. Dr Rimoin was to become his co-investigator for the next 40 years, but even more so, his good friend. They both realized that they had common interests in syndromes, the evolving field of genetics, and especially in the radiological-oriented area of skeletal dysplasias. This commonality of interests led to the evolution of the International Skeletal Dysplasia Registry. Dr Lachman has published over 250 research papers in peer-reviewed journals. He has authored several books and book chapters. Recently, he solely completed the 5th edition of Taybi and Lachman's *Radiology of Syndromes, Metabolic Disorders and Skeletal Dysplasias*, which has recently been released. Dr Lachman has been on the UCLA faculty for the last 40 years. He has been Professor Emeritus since 1999. Recently, he was appointed Visiting Scholar and then Clinical Professor at Stanford University. He has served for many years as medical advisor for the Little People of America.

**David L Rimoin MD, PhD** During the final preparation of this book, we lost a major pioneer in the field of Medical Genetics: David L Rimoin, MD, PhD. Dr. He died May 27th, 2012 following a diagnosis of pancreatic cancer only a few days earlier, having seen patients even on the Tuesday before he died. Dr Rimoin's achievements as Steven Spielberg Chair and Director of the Medical Genetics Institute at Cedars-Sinai, as the former Chairman of the Department of Pediatrics and Professor of Medicine and of Pediatrics at UCLA and founding director of the multi-campus UCLA Genetics Training Program, were profound. Children, adults and families from across the country and the world who turned to him for his medical expertise have lost a uniquely skilled and caring physician who was singularly devoted to their health and wellbeing. His medical contributions will continue to bring healing for generations --through the books he authored, his leadership and mentoring, the papers he presented, his lectures and speeches, and through the research that gave birth to lasting medical progress. We honor David Rimoin's passion for excellence, scholarship, innovation, his contributions to transformational medicine and his ceaseless kindness and integrity.

## Abnormalities of Bone Structure

*William A Horton*Director of Research, Shriners Hospital for Children, Professor of Molecular and Medical Genetics,  
Oregon Health and Science University, Portland OR, USA**GLOSSARY**

**Endochondral ossification** – a type of bone formation in which bone is first generated as a cartilage template, which is subsequently replaced by bone proper. It is responsible for the formation and growth of most of the skeleton.

**Loss of heterogeneity** – this occurs when there is loss of normal function of one allele of a gene in a cell in which the other allele is already inactivated. In genetic disease, loss of the first allele is usually inherited, while loss of the second allele results from somatic mutation.

**Membranous ossification** – a type of bone formation in which bone is generated directly from fibrous mesenchymal or bone tissues with no cartilage template. The calvaria, clavicles, body of the mandible, spinous processes of the vertebrae, and part of the pelvis arise in this fashion.

**Somatic mosaicism** – when gene mutations cause genetic disease, they typically arise in the sperm or egg and are present in all cells of the affected individual. However, mutations can sometimes occur later in embryologic development and only in somatic cells (non-germ cells). In this case, the individual has two populations of somatic cells, normal and mutant, and disease occurs only in the tissues and cells derived from the mutant cells.

**159.1 INTRODUCTION**

In the past few decades, many disorders have been delineated that are characterized by abnormal skeletal development, collectively termed the skeletal dysplasias. Many of these, designated the osteochondrodysplasias, are thought to result from disturbances in the normal ossification process. The osteochondrodysplasias have been subdivided into three categories: defects of growth of tubular bones and/or spine, disorganized development of cartilage and fibrous components of the skeleton, and abnormalities of density of cortical diaphyseal structure and/or metaphyseal model (1). The disorders comprising the second category are the subject of this chapter. They can best be understood in the context of the normal ossification process.

The skeleton normally develops and grows through a combination of two distinct forms of ossification:

endochondral and membranous (2). In the latter form, bone develops directly from fibrous tissue. The calvaria, clavicles, body of the mandible, spinous processes of the vertebrae, and part of the pelvis arise in this fashion. In addition, diaphyseal widening of individual bones occurs in this manner. The remainder of the skeleton develops through endochondral ossification, a more complex process in which a cartilage model for each bone is formed and is subsequently transformed into true bone. The cartilage anlagen arise early in embryonic development, and by mid-pregnancy, ossification has spread throughout each bone, leaving only the epiphyses as cartilaginous structures. Continued proliferation and hypertrophy of the cartilage bordering the ossification front (the endochondral growth plate) is responsible for linear growth of the bone. Highly organized zones of proliferative and hypertrophic cartilage can be identified within the growth plate. As the slowly progressing ossification front penetrates the cartilage at the cartilage–bone interface, true bone is laid down. Initially, it is immature or woven bone, but with modeling it is replaced by mature or lamellar bone (The maturation process occurs in membranous ossification as well.) Secondary centers of ossification, which exhibit a similar sequence of events, also develop in the epiphyses during late fetal life and throughout childhood. With completion of puberty, growth plate activity ceases and the structure is transformed into bone.

Certain generalizations can be made about the disorders discussed in this chapter. Several of them, such as hereditary multiple exostoses or enchondromatosis, are characterized by aberrant growth plate activity. The lesions in these disorders are restricted to bones that arise by endochondral ossification. The activity of these lesions tends to parallel that of the normal growth plate (i.e. growth during childhood, quiescence after puberty). By contrast, bone maturation is disturbed in some of the other disorders, such as fibrous dysplasia of bone. Puberty seems to have little effect on these lesions, which may affect all bones. Thus, the clinical features in these disorders are often determined by the relationship of the specific abnormality to the normal ossification process.

## 159.2 DYSPLASIA EPIPHYSEALIS HEMIMELICA

Dysplasia epiphysealis hemimelica (DEH) is a developmental disorder of childhood characterized by asymmetrical growth of epiphyseal cartilage. Originally described as tarsomegalie in 1926, several designations have been used: tarsoepiphyseal aclasis, chondrodys-trophy epiphysairi, benign epiphyseal osteochondroma, carpal osteochondroma, osteochondroma of the distal femoral epiphysis, epiphysealis hyperplasia, and intra-articular osteochondroma of the astragalus (3,4). The term DEH was introduced by Fairbank (1956) to distinguish this condition from multiple epiphyseal dysplasia and chondrodysplasia punctata. DEH has been extensively reviewed by several authors (3–7).

Males are affected approximately three times as often as females. Symptoms usually arise between the ages of 2 and 14 years but have been described as early as 18 months (8). In a few cases, the diagnosis has been established during adulthood. Joint deformity, especially at the knee and ankle, restricted motion, and occasionally pain call attention to the condition. Bony hard swelling is found at the sites of the lesions, which are usually confined to one side of a limb. The medial side is mainly affected in the leg, whereas in the arm, which is involved infrequently, the radial side predominates. The most common sites in order of decreasing frequency are talus, distal femoral epiphysis, distal tibial epiphysis, proximal tibial epiphysis, tarsal navicular, median cuneiform, and distal fibular epiphysis. The axial skeleton is rarely involved, but lesions of the pubis (3), acetabulum (9), and scapula (10) have been reported. Multiple lesions occur in about two-thirds of the patients.

Skeletal radiographs reveal irregular enlargement of the affected epiphyses and tarsal and carpal bones. There is usually a lobulated multicentric mass adjacent to one side of the epiphysis or bone. In young children, multiple ossification centers may be seen within this mass, but with time these fuse to form a single ossified mass that eventually becomes part of the adjacent bone. Mild widening of the metaphyses of affected bones may also be seen. When the talus is affected, the ossification centers may appear prematurely. Magnetic resonance imaging (MRI) may be useful to define the extent of the lesions (11).

Histologic examination of the lesions shows nests of proliferating and hypertrophic chondrocytes surrounding ossification centers. The appearance resembles that seen at secondary ossification centers; it is also indistinguishable from the pattern observed in osteochondral exostoses.

The lesions and their secondary deformities tend to increase during the first few years of life, after which they become somewhat quiescent and enlarge only slightly as the child continues to grow. Both shortening and lengthening of the affected limbs compared with unaffected limbs has been described. New ossification centers may

appear radiographically; however, as described earlier, these fuse with each other and the normal portion of the bone. After puberty, there is little change. Treatment must be individualized and usually involves excision of the lesions that contribute to deformities and interfere with normal function. Malignant degeneration of the lesions has not been described.

All cases of DEH reported to date have been sporadic. Moreover, in one instance, one of a pair of monozygotic twins was affected (12). Hensinger et al. (1974), however, reported the autosomal dominant transmission of DEH together with intracapsular chondromas, extraskeletal chondromas, and osteochondromas (13).

## 159.3 HEREDITARY MULTIPLE EXOSTOSES

The formation of many cartilage-capped exostoses that give rise to deformities of the growing skeleton characterizes hereditary multiple exostoses. The syndrome has been recognized as a familial entity for more than a century. Many terms, including diaphyseal aclasis, multiple osteochondromas, multiple osteochondral exostoses, hereditary deforming osteochondrodysplasia, and multiple exostoses, have also been applied to it.

The clinical and radiographic features have been delineated by Solomon and Crandall et al. (14–16). The vast majority of patients are discovered during the first decade of life, often by the age of 2 years. Bony lumps of the scapula and tibia are usually noted first, probably because of the conspicuous nature of these areas. Skeletal radiographs at this time, however, usually show lesions in other bones. Palpable masses have been detected soon after birth in affected infants known to be at risk for the condition. The lesions characteristically appear and increase in size during childhood. After completion of puberty, no new lesions form, and the activity of existing lesions ceases. Asymptomatic ones may be detected by radiograph at any age. In addition, some lesions may actually disappear with time. The lesions are juxtaepiphyseal in origin and most frequently reside at the ends of tubular bones, vertebral borders of the scapula, iliac crest, and ribs. Involvement of vertebral bodies, patella, and carpal and tarsal bones is rare; however, the lesions can arise in any bone that develops by endochondral ossification. The radiographic appearance of the individual lesions varies considerably. In general, they appear as projections of the bone from which they come, the overlying cortex and inner marrow cavity are continuous with those of the parent bone.

The earliest lesion viewed radiographically is an asymmetrical overgrowth of the metaphyseal cortical bone, which lies immediately adjacent to the growth plate. As the parent bone lengthens, two patterns may evolve. Normal growth of the juxtaepiphyseal metaphyseal bone may resume, so that the exostosis appears to migrate toward the diaphysis as the bone elongates (Figure 159-1).

**FIGURE 159-1** Radiograph showing exostosis of the diaphysis of the humerus in a 16-year-old boy with hereditary multiple exostoses.

Alternatively, the exostosis may continue to expand at the metaphysis, producing an irregular club- or sometimes cauliflower-shaped end of the bone ([Figure 159-2](#)). Pedunculated lesions, which point away from the joint, may also be seen near the metaphysis. The behavior of the lesions is unpredictable, varying from one bone to another within the same individual and even within the same bone ([14](#)).

In two-thirds of patients, the clinical picture is dominated by skeletal deformities distinct from the actual exostoses. They result from reduced linear growth of the affected long bones. In a study of 76 patients, Solomon (1961) found that forearm deformities including bowed radius, conical ulna, and radiohumeral dislocations were present in 50% of patients, whereas genu valgum, valgus deformities of the ankles, and deformities of the hands were present in 21%, 45%, and 17%, respectively ([17](#)).

**FIGURE 159-2** Radiograph showing exostosis of the proximal humerus in an 18-year-old woman with hereditary multiple exostoses.

Except for the valgus deformities of the ankles, these deformities were asymmetrical. Scoliosis and pelvic and thoracic deformities were occasionally found as well. Short stature due to shortened extremities was common (41%) but was rarely severe. Shapiro et al. (1979) noted frequent limb length discrepancies ([18](#)). Crandall et al. (1984) estimated that half of affected persons are moderately or severely handicapped ([16](#)).

The most serious complication of this syndrome is malignant degeneration of the exostoses. Although development of chondrosarcoma has been reported in as many as 25% of patients ([19](#)), the actual incidence is probably much lower, in the range of 3–10% of patients ([20–22](#)). Some families may be more prone to malignant degeneration than others ([16](#)). The tumors tend to occur in the pelvic girdle, most commonly arising from the ilium or proximal femur, and less often in the shoulder girdle. The diagnosis is most frequently made in the early 30s, and the first signs are usually swelling and, rarely, pain or neurologic symptoms ([21](#)). The tumors generally grow slowly and metastasize late. Because the

exostoses do not normally enlarge after completion of puberty, any swelling or pain associated with the lesion, especially in the pelvic or shoulder region, should suggest malignant change. Other rare complications include large pelvic exostoses that cause urinary obstruction and renal failure, malposition of a pregnant uterus, intestinal obstruction, and spinal cord compression (14,23).

Treatment depends on the particular deformities and complications that occur, although most patients require surgery. The most common procedures include removal of exostoses that interfere with function, contribute to deformity, produce compression, or are suspected of undergoing malignant degeneration; epiphysiodesis to compensate for reduced growth of affected bones; excision of the radial head in cases of humeroradial dislocation; and correctional osteotomies for specific deformities (18).

Examination of an exostosis histologically shows a projection of trabecular bone covered by a cartilage cap. In children and adolescents, columns of normally appearing proliferating and hypertrophic chondrocytes are found along the bony margin. The appearance is very similar to a normal growth plate except that the cartilage–bone interface is irregular, and collections of hypertrophic chondrocytes are found in the bone (24). In the adult, the cartilage is reduced to a thin rim or is absent altogether.

Hereditary multiple exostoses is inherited as an autosomal dominant trait. When studied radiographically, there is essentially complete penetrance. Males and females are equally affected, but there is slight tendency toward similarity in the distribution and type of lesions and deformities within families (15). Three genetic loci have been identified to date (25–28). In most families, the condition maps to chromosome 8q24.11–q24.13, the region to which the Langer–Giedion syndrome has been localized (see section 159.4), which has been designated *EXT1*. A number of mutations have been found in *EXT1* and to lesser extent in *EXT2*, which maps to chromosome 11p11–p13 (29–37). The risk of malignant degeneration is greater for patients with mutations of *EXT1* compared to those with *EXT2* mutations (38). The third locus maps to chromosome 19p, but it is a minor locus for hereditary multiple exostoses (39,40).

The mechanism by which *EXT* mutations cause exostoses is not well understood. However, the detection of loss of heterozygosity for the *EXT* loci in tumors, combined with the loss-of-function in the reported mutations, suggests that the *EXT* gene products function as tumor suppressors (31,33,37,41,42). *EXT1* and *EXT2* encode type II transmembrane glycoproteins that were first identified in the endoplasmic reticulum in association with glycosyltransferase activity (43,44). It appears that complexes containing products of both *EXT1* and *EXT2* and localized to the Golgi apparatus constitute the active glycosyltransferase enzyme(s), which are involved in the synthesis and polymerization of heparan sulfate (45,46). Disturbances in cell surface heparan sulfate may interfere with signaling

involving hedgehog proteins and potentially other growth factors (47). In fact, Koziel et al. have proposed that development of exostoses in this syndrome reflects local activation of Indian hedgehog signaling (48). Mouse modeling experiments have established that clonal homozygous inactivation of *Ext1* in growth plate chondrocytes leads to osteochondromas typical of human exostoses (49,50). These findings implicate clonal loss of heterozygosity for *EXT1* or *EXT2* in these cells as the mechanism responsible for exostoses in humans. Presumably the resulting loss of glycosyltransferase enzyme activity and disturbance of heparan sulfate synthesis disturbs the local regulatory circuits that modulate the fate of these cells.

#### 159.4 LANGER–GIEDION SYNDROME

In Langer–Giedion syndrome, multiple exostoses occur as a component of a multisystem disorder. Also known as the trichorhinophalangeal (TRP) syndrome type II and acrodysplasia with exostoses, this syndrome is rare. The first two cases were described independently by Langer (1968) and Giedion (1969) (51,52). Hall, together with Langer, Giedion, and others, reported five additional patients and delineated the syndrome in 1974 (53). Several more cases have been added to the literature (54–62). Heavy eyebrows, large bulbous nose with thickened alae and septum, prominent elongated philtrum, and thin upper lip together with mild microcephaly, large poorly developed protruding ears, and sparse scalp hair give rise to a characteristic craniofacial appearance. Other consistent features have included mental retardation, delay in the onset of speech, short stature, multiple exostoses, cone-shaped epiphyses, and loose skin. The mental retardation is generally mild to moderate in degree. In one patient who was initially considered to be mentally retarded, intelligence was eventually determined to be normal after a profound hearing deficit was found (57). A hearing loss has been detected in half the patients tested. The delay of speech development has been observed in at least two patients with normal audiograms, however, and it appears to be out of proportion to the degree of mental retardation.

The multiple exostoses are similar in clinical behavior and radiographic appearance to those seen in hereditary multiple exostoses. Diminished linear growth of affected bones and secondary deformities occur as well. No cases of malignant degeneration have been reported, but most of the patients described to date have been children.

Several types of cone-shaped epiphyses have been described by Giedion (1969) (52). All patients with this syndrome have had the type 12, in which the distal epiphyses of the metacarpals and proximal epiphyses of the phalanges of the hand are affected. Small conical-shaped epiphyses appear to invaginate into the adjacent metaphyses, often with fusion and widening of the metaphyses (53). These abnormalities are not visible radiographically before the age of 3–4 years, however, because ossification

of the epiphyses in the hand bones is insufficient before this age. Epiphyseal irregularities have been found in other parts of the skeleton. In particular, Perthes-like changes in the capital femoral epiphyses have been seen in half the patients. This generalized epiphyseal disturbance is probably responsible for the short stature exhibited in all the cases.

The occurrence of multiple fractures has been mentioned as a component of the syndrome; however, it has been demonstrated in only three of the thirteen patients. Moreover, one patient had only a single traumatic fracture of the humerus (63), and the two others were identical twins who showed generalized skeletal demineralization. In fact, Hall et al. (1974) questioned whether this feature was a part of the syndrome or simply a second abnormality restricted to the twins (53).

Although most of the children have cutaneous involvement, it has varied with age. The loose skin seems to be most striking during early childhood and regresses or even disappears between the ages of 6 and 14 years. Small, brown to black maculopapular nevi are found on the face, scalp, neck, and upper trunk of the older children but have not been seen before age 4 years.

Small deletions of the long arm of chromosome 8 (q24.11–q24.13) have been identified in most patients with Langer–Giedion syndrome in whom high-resolution banding has been done (58,60,62,64). Such studies initially confused the nosology of the TRP syndromes, however, because deletions typical of TRP type II have been detected in two patients with clinical and radiographic features of TRP type I (61,65). Ludecke et al. (1991) showed that 15 of 16 patients had loss of genetic material; the shortest region of deletion overlap was estimated to be less than 2 Mb (66). It was subsequently shown that both the *EXT1* gene and the gene mutated in TRP syndrome types I (*TRPS1*) and III reside within the region deleted in Langer–Giedion syndrome (30,67–70).

### 159.5 ENCHONDROMATOSIS

Enchondromatosis is another rare disorder of the developing skeleton. It was originally described by Ollier, who called it dyschondroplasia, but it has been variably referred to as Ollier disease, multiple enchondromatosis, multiple enchondromas, and internal enchondromatosis (71). It must be distinguished from a similar but yet distinct disorder, Maffucci syndrome, in which the combination of multiple enchondromas and cutaneous hemangiomas and other tumors is found.

The manifestations of the disorder result from the occurrence of cartilaginous tumors in the metaphyses of bones that are formed in cartilage. They have been best described by Fairbank (1948) (71). Both long and short tubular bones are preferentially involved, and the more rapidly growing ends of these bones are the most frequently affected sites. For example, lesions in the region of the knee joint and at the lower ends of the

radius and ulna are particularly common sites, whereas the phalanges and the pelvis are somewhat less common. The scapula, ulna, ribs, sternum, base of the skull, and facial bones are rarely affected, and the cuboid bones (e.g. the vertebrae, carpal, and tarsal bones) usually escape. Tumors do not occur in the calvaria. By definition, more than one lesion must be present; however, the involvement may vary considerably from enchondromas affecting a single limb to tumors throughout the skeleton. In the latter instance, the lesions are asymmetrical and bilateral in most cases (72).

The characteristic deformities result from direct expansion of the tumors and from reduced linear growth of the affected bones. The most common deformities include phalangeal enlargement, asymmetrical shortening of the limbs, bowing of the long bones, ulnar deviation of the wrist, dislocation of the radial head, and genu valgum. In rare instances when the base of the skull is involved, facial asymmetry and cranial nerve compression may occur. Fractures of the affected bones are uncommon. Considerable variability has been noted regarding the severity of the deformities, ranging from asymptomatic lesions detected only by radiographs to extensive disfigurement and disability (e.g. massive swelling of fingers and toes).

The disorder is usually detected during childhood but has been identified at birth in an infant who exhibited asymmetrical limb shortening (72). The appearance of new lesions as well as tumor growth and progression of deformities occurs in an unpredictable fashion during childhood. The lesions often regress and deformities stabilize after puberty. Renewed growth during adulthood suggests sarcomatous degeneration. The occurrence of this complication is probably less than in Maffucci syndrome (see Section 159.6), but actual figures are not known.

Radiographically, the lesions vary from minute foci of incompletely calcified epiphyseal cartilage extending linearly from the growth plate into the metaphysis of the bone to large tumorous masses of cartilage that produce extensive metaphyseal enlargement (Figure 159-3). Irregular calcifications are often found within the tumor. Thinning and disruption of the cortex of the overlying bone may occur; and there may be abnormal metaphyseal modeling. In addition, radiolucent defects often extend into the shaft of the bone (73). The radiographic changes of enchondromatosis may be influenced by age (72). For example, despite shortening of a bone, typical lesions may not be seen during infancy. Furthermore, there may be a gradual “filling in” of the lesions with normal-appearing bone after puberty.

The tumor pathologically consists of lobulated masses of irregularly dispersed chondrocytes encased within bone. Proliferative and hypertrophic cells are found, and some areas resemble the normal endochondral growth plate. In tissue from older patients, intracartilaginous ossification may be seen (24).

Enchondromatosis has occurred in a sporadic fashion in almost all cases reported to date. Both sexes

**FIGURE 159-3** Radiograph showing enchondromas in distal femur and proximal and distal tibia and fibula in a 12-year-old boy with enchondromatosis.

are affected, but it is more common in males (71). The source of the metaphyseal enchondromas is not known, although an activating mutation of the parathyroid hormone/parathyroid-hormone-related protein (PTH/PTHrP) type I receptor (*PTHr1*) has been identified in a few patients or tumors (74,75). Expression of the mutant receptor in vitro and in transgenic mice constitutively activated Indian hedgehog signaling and produced enchondromal-like lesions, raising the possibility that enchondromas could result from somatic *PTHr1* mutations.

### 159.6 MAFFUCCI SYNDROME

In 1891, an Italian, Maffucci, described a patient with enchondromas and superficial hemangiomas. Today, the syndrome in which this combination occurs bears his name, however, it is recognized that the manifestations are much more extensive. The skeletal manifestations are similar to those seen in isolated enchondromatosis. Expanding cartilaginous tumors in the metaphyses of tubular bones, primarily, develop during childhood. The metacarpals and phalanges of the hand are the most common sites, although lesions are frequently observed in the tibia, fibula, femur, radius, ulna, and humerus as well (76). The tumors tend to be asymmetrical and bilateral and cannot be distinguished radiographically or histologically from those found in patients with enchondromatosis. Likewise, tumor expansion and shortening of involved bones lead to a similar array of deformities. Spontaneous fractures through areas of advanced rarefaction have been reported in 26% of patients in one series (77). Cranial nerve palsies due to involvement of the base of the skull have also been described (78).

The major non-skeletal manifestation of the disorder is the occurrence of simple or cavernous cutaneous hemangiomas (77,79). Usually located on the limbs, they lie in the deep layers of the skin and subcutaneous tissues. Their size varies from a few millimeters in diameter to many centimeters. They are not limited to the skin but may also be found throughout the viscera. There is a slight tendency for the hemangiomas and enchondromas to show a similar distribution with regard to laterality, but no direct relationship exists between the two. Phlebectasia is commonly observed, and thrombosis and subsequent calcification often occur within vascular spaces. In fact, phleboliths seen on radiography are found in nearly half the patients with this condition (77). In reporting a patient with enchondromas and fibromuscular dysplasia of cerebral arteries, Slagsvold et al. (1977) speculated that this arterial lesion might represent another vascular manifestation of the disorder (80). Lymphangiomatosis has been described in several cases (76,78). Other non-skeletal manifestations seen in the Maffucci syndrome include vitiligo, hyperpigmentation, and nevi (78). Most soft tissue lesions are painless, although mild discomfort as well as increased skin temperature may accompany the hemangiomas (76).

The skeletal abnormalities do not usually present until early or mid-childhood, but the hemangiomas are often detected at or shortly after birth. The clinical picture through puberty is dominated by the skeletal lesions; as with enchondromatosis, it is unpredictable. After the completion of puberty, however, the enchondromas do not usually progress, although this is not invariable (77).

A predisposition to neoplasia during adulthood is well established. The greatest risk is for sarcomatous degeneration of the enchondromas, which has been estimated to occur in 15–30% of patients (76,77,79,81,82). The

risk does not correlate with the severity of involvement. Malignant degeneration of hemangiomas and lymphangiomas also occurs, and patients may develop multiple primary tumors. There are also reports of many other malignant and benign tumors occurring in patients with Maffucci syndrome. These include osteosarcoma, cartilaginous hamartoma, fibrosarcoma, glioma, mesenchymal ovarian carcinoma, carcinoma of the pancreas, uterine polyps and fibroids, adrenal cortical adenomas, thecoma of the ovary, multiple fibromas, and leukemia (75,76,81–85). Chromophobe adenoma of the pituitary has been noted in seven of 114 reported cases (86). Because of the isolated nature of many of these reports, it is not clear if these associations are significant or simply coincidental. Sudden enlargement of either skeletal or non-skeletal tumors during adulthood, however, should make one suspicious of malignant degeneration.

The treatment consists of orthopedic and surgical intervention to minimize deformities and for cosmetic purposes. Careful surveillance for malignant degeneration of both skeletal and non-skeletal tumors, especially in the brain and abdomen, is essential.

Maffucci syndrome occurs in all races with equal sex distribution. All cases have been sporadic, and affected women have produced unaffected offspring (76). Normal karyotypes have been obtained in several instances (76). To explain the many mesenchymal tumors, it is generally thought that the syndrome results from a generalized defect in the mesodermal tissues (76–78); however, the nature of this defect is unknown.

### 159.7 METACHONDROMATOSIS

Metachondromatosis is a distinct syndrome in which both exostoses and enchondromas are found. Only a few cases have been reported. Thirteen were members of three families in which the trait showed autosomal dominant transmission (87–89). Other cases have been described by Lachman et al. (1974), Keret and Bassett (1990), Wenger et al. (1991), Ikegawa et al. (1992), and Wittram and Carty (1995) (90–94).

Clinically, patients may be short and usually present with exostoses, preferentially affecting the tubular bones of the hands and feet. In contrast to the lesions seen in hereditary multiple exostoses that point away from the epiphyses, the exostoses in this syndrome point toward the joint. In addition to the exostoses, irregularly calcified lesions that are sometimes separated from bone have been observed near the epiphyses (88). An unusual feature of the syndrome is the tendency for the tumors to regress and actually disappear in adulthood (87–89).

The enchondromas are found in the metaphyses of long bones and in the iliac crest, which is an unusual location for the tumors in enchondromatosis and Maffucci syndrome (Figure 159-4). Irregularity of the endplates of the vertebral bodies has also been seen. Presumably, this defect, together with the metaphyseal involvement

**FIGURE 159-4** Anteroposterior radiograph of pelvis showing enchondromas in both iliac crest and exostoses of femoral necks in an 8-year-old with metachondromatosis. (Courtesy of R. S. Lachman, Los Angeles, CA.)

by enchondromas, is responsible for the short stature. Avascular necrosis of the capital femoral epiphysis has been reported in a few cases (91–93). The risk of malignant degeneration of the cartilaginous tumors is not known.

Loss-of-function mutations of *PTPN11* (protein tyrosine phosphatase, non-receptor type 11), which encodes the protein tyrosine phosphatase SHP2, have been detected in two multigenerational families with metachondromatosis (95). *PTPN11* functions as a regulator of the RAS/MAPK pathway downstream of many receptor tyrosine kinases. Mutations of *PTPN11* have been identified in the Noonan, Noonan-like, and LEOPARD syndromes.

### 159.8 FIBROUS DYSPLASIA OF BONE

Fibrous dysplasia of bone is characterized by the replacement of bone by dysplastic fibrous tissue. Although initially confused with osteitis fibrosa cystica of hyperparathyroidism, it was recognized as a separate entity in 1937 by Albright et al., who described the skeletal lesions in association with increased skin pigmentation and endocrine disturbances (96). Five years later, Lichtenstein and Jaffe (1942) delineated the pathologic features of the skeletal lesions, which they termed fibrous dysplasia of bone, and observed that the extraskeletal abnormalities did not occur when only a single bone was involved (97). The disorder has since been defined further by several reviews in which the clinical and radiographic features of nearly 300 patients have been examined (98–104). Although there has been a tendency to classify fibrous dysplasia on the basis of whether extraskeletal features are found, it appears more appropriate to divide it on the basis of whether the lesions involve one or more than one

bone, because the extraskeletal features occur only in the latter instance.

Hypotheses that the lesions of this condition result from autonomous hyperplasia of multiple endocrine glands and other tissues due to disturbed regulation of cyclic adenosine monophosphate (cAMP) (105–109) and that they reflect mosaicism of a dominant gene mutation (110) evolved in the 1970s and 1980s. Both proved to be correct. It is now clear that the disorder results from mutations of the gene encoding the heterotrimeric signal transducer guanine nucleotide-binding protein, alpha-stimulating activity polypeptide 1 (GNAS1), which couples cell surface receptors to adenylyl-cyclase-dependent downstream pathways (111–115). Substitution of either histidine or cysteine for arginine at position 201 of GNAS1 leads to ligand-independent activation of relevant signaling pathways. It should be noted that loss-of-function mutations of *GNAS1* are found in patients with Albright hereditary osteodystrophy.

Current dogma holds that all fibrous dysplasia patients with activating *GNAS1* mutations exhibit somatic mosaicism (115,116). If the mutation occurs early in life, mutation-bearing cells are likely to reside in many locations, giving rise to polyostotic fibrous dysplasia and extraskeletal lesions of McCune–Albright syndrome. Monostotic lesions reflect isolated somatic mutations in bone cells that occur later in life.

### 159.8.1 Monostotic Fibrous Dysplasia

Patients with monostotic disease are thought to be much more common than those with the polyostotic form. All cases have occurred on a sporadic basis. Males and females are equally affected. The most frequently affected sites in monostotic fibrous dysplasia are the craniofacial bones, including the skull, maxilla, and mandible; ribs; femur; tibia; and humerus. The pelvis, other long bones, vertebrae, and tarsal bones are occasionally involved (99,103,104). The lesions in the extremities usually present during adolescence with pain, swelling, and pathologic fractures. The craniofacial lesions are often heralded by swelling, asymmetrical growth of the skull or face, and occasionally unilateral proptosis; they tend to occur in the second and third decade. Rib lesions are often asymptomatic and may be discovered at any age, often as an incidental finding on a chest X-ray (104).

The earliest radiographic change consists of a loss of density at the site of the lesion. Later, there is expansion of the bone with erosion and thinning of the cortex from within. The shaft may exhibit a “ground-glass” appearance, on which prominent trabecula are superimposed. In long bones, the lesions appear to begin in the metaphysis and extend into the diaphysis (101). Sclerosis may be associated with involvement of the facial bones.

The lesions tend to grow slowly before adolescence; however, their activity is variable (117,118). After

puberty, they usually become inactive, but Henry (1969) observed that several patients developed symptoms, often pathologic fractures of long bones, beyond this age (104). He also noted fibrous dysplasia may become activated or reactivated during pregnancy. Malignant degeneration does occur but rarely. Schwartz and Alpert (1964) calculated the incidence to be approximately 0.4% of patients (119). Osteogenic sarcoma was the predominant tumor and occurred at an average age of 32 years, following a mean lag time of 13.5 years after the initial presentation. Several of the patients in whom malignant degeneration occurred have received previous radiation therapy (99,119,120).

Although the radiographic appearance of fibrous dysplasia is characteristic, it is not pathognomonic. Therefore, in the monostotic form, a biopsy is necessary to confirm the diagnosis. Histologically, the lesions consist of poorly defined, partially calcified trabecula of bone embedded within dense cellular fibrous tissue. The bone is immature (woven) in type; no lamellar (mature) bone is found. The trabecula are rimmed by only a few osteoblasts, and there is a paucity of osteoclasts (24,98,99,102). These changes seem to vary little with age. Cysts, dense fibrosis, islands of cartilage, and lamellar transformation of woven bone have also been described. Although some of these changes may be the consequence of previous surgery and trauma (102), they largely reflect the effects of constitutive activation of cAMP-dependent signaling pathways in bone cells. The effects include enhanced proliferation, and reduced and inappropriate osteoblastic differentiation (114,121,122).

Conventional treatment of monostotic fibrous dysplasia involves surgery to remove abnormal tissue. If this is not possible, curettage of the lesion and packing it with bone chips is indicated. Treatment is successful when the lesion is completely removed. However, if not, recurrence is common. Infusion of the bisphosphonate pamidronate may provide an effective alternative treatment (123).

### 159.8.2 Polyostotic Fibrous Dysplasia

In polyostotic fibrous dysplasia, McCune–Albright or Albright syndrome, bone lesions that are identical to those found in the monostotic form of the disease occur in multiple bones, in association with abnormal skin pigmentation and a variety of endocrine disturbances. The bone lesions are the only invariable component of the syndrome as classically defined. They are found throughout the skeleton, although the most frequent sites are the femur, tibia, pelvis, phalanges, ribs, humerus, and base of the skull (99). The radiographic appearance of the extracranial lesions is essentially the same as seen in monostotic fibrous dysplasia (Figure 159-5). Cranial involvement is usually characterized by diffuse sclerosis of the base of the skull, often involving the sphenoid, sella turcica, and roof of the orbit, together with thickening

**FIGURE 159-5** Radiograph showing fibrous lesions in the proximal tibia in a 14-year-old girl with polyostotic fibrous dysplasia.

of the occiput and obliteration of the paranasal sinuses. Radiolucent areas may be scattered through these areas of increased density.

The bone lesions are usually evident by the age of 10 years, and patients most often present with a limp, leg pain, or fracture (99). Deformities are common; they include leg length discrepancy, coxa vara, shepherd's-crook deformity of the femur, bowing of the tibia, Harrison's groove, and protrusio acetabuli. Most patients have at least one fracture, and many have repeated ones. Extensive craniofacial involvement may produce facial deformities as well as cranial nerve compression, hearing loss, sinusitis, and lacrimal duct obstruction (100). Spinal cord compression has been associated with vertebral involvement (124). The progression of the deformities is often associated with the extension of existing lesions. Puberty seems to have no effect on such extension or on the incidence of fractures. New lesions may appear, usually after puberty, and spontaneous improvement rarely occurs (99). An elevation of serum alkaline phosphatase may be found.

Malignant degeneration has been reported more often in polyostotic than in monostotic fibrous dysplasia (119). It is thought that the higher incidence in the former is due to the greater number of lesions; the risk per lesion is the same in both (118). The risk is relatively low, 0.4% of patients, and the complication occurs less often in the craniofacial region than in other parts of the skeleton (100). Several of the patients with this complication have received prior radiation therapy (118).

The extraskeletal manifestations of polyostotic fibrous dysplasia involve the skin and endocrine glands. The cutaneous lesions consist of flat patches of brown pigmentation. They follow an irregular contour and are frequently evident at birth. They may be extensive and may, but not necessarily, overlie the bone lesions (125).

Sexual precocity occurs in about one-third of patients, mostly females. In contrast to the sequence of events seen in normal girls undergoing puberty and in most types of sexual precocity, vaginal bleeding usually occurs first and may precede breast development and the appearance of axillary and pubic hair by many years (126). It may appear as early as 3 months of age. The early bleeding is usually scant and irregular, and normal menstrual periods begin at the time of expected puberty. Moreover, fertility appears to be unaffected (125). Accelerated skeletal maturation accompanies the sexual precocity. Laboratory findings in patients have been difficult to interpret. Girls with precocious puberty have larger than normal ovaries containing cysts (107). Gonadal and adrenal steroids have been found to be elevated in the plasma (105,107); however, both low and high levels of circulating gonadotropins have been observed (105,107,126,127). Benedict (1962) noted that in three such cases in which ovarian tissue had been examined, no evidence of ovulation was found (126). However, active spermatogenesis was seen in a testicular biopsy from a 6-year-old boy with this condition (128).

Hyperthyroidism is a common feature, occurring in 30% of patients in one series (126). It may also contribute to the accelerated skeletal maturation. The thyroid abnormality is mild and distinct from Graves' disease in that ocular changes are lacking, and histologically there is no lymphocytic infiltration in the thyroid tissue. Instead, diffuse hyperplasia is found (128). Thyroid-stimulating hormone levels have been determined as being low on three occasions (129). Features of acromegaly and pituitary gigantism have been described several times, and an elevation of growth hormone has been detected at least once (127,128). Cushing syndrome due to bilateral adrenal hyperplasia has been documented at least five times (105,130,131). Hyperparathyroidism has been observed twice (103,132).

As discussed earlier, this condition usually results from postzygotic activating mutations of arginine 201 in *GNAS1* leading to a mosaic distribution of cells bearing constitutively active adenylate cyclase activity. With the delineation of its genetic basis, the clinical spectrum of this condition has been expanded to include severely ill infants with hepatobiliary disease, cardiac disease, isolated peripheral precocious puberty and other nonendocrine and non-skeletal manifestations. These infants and children would not ordinarily be suspected to have McCune–Albright syndrome but were found to have the same mutation observed in other patients with typical features of the syndrome

(115,133). In a 2004 assessment of 113 patients presenting with the classic triad of polyostotic fibrous dysplasia, café-au-lait skin pigmentation and precocious puberty (24%), two of the triad (33%) or only one feature (40%), the activating mutation was detected in 43%. Mutation detection increased to 90% when affected tissue was available for analysis, although skin lesions were positive for mutation in only about one-fourth of instances. The mutation was found in 46% of blood samples from patients presenting with the classic triad of manifestations, 21% of patients with two signs, and 8% of patients with a single feature (115). These observations indicate that affected tissue should be analyzed for mutation if possible.

Other abnormalities have rarely been observed in patients with polyostotic fibrous dysplasia and may be components of the syndrome. Multiple intramuscular myxomas have been noted in 11 patients (134,135). They tend to develop in clusters, especially in the thigh region, and usually present during adulthood. Hyperplasia of reticuloendothelial tissue and both lymphoid and myeloid metaplasia have also been described (129).

Surgical correction may be useful for skeletal deformities (136). Although still somewhat controversial, voral alendronate, appear to be effective in reducing bone turnover and alleviating pain in this disorder (137–140).

### 159.9 CHERUBISM

In 1933, Jones reported four sibs with an unusual facial appearance; they appeared to be looking toward the heavens. He coined the term cherubism. Despite the introduction of many descriptive designations, including familial multilocular cystic disease of the jaws, familial fibrous dysplasia of the jaws, familial fibrous swelling of the jaws, familial bilateral giant-cell tumor of the jaw, familial intraosseous fibrous swelling of the jaw, disseminated juvenile fibrous dysplasia of the jaws, and familial osseous dysplasia of the jaws, the term cherubism seems to be firmly established (141).

By 1970, more than 70 cases had been described. The clinical features of cherubism vary considerably (141–143). In general, the affected children present with painless symmetrical swelling of the jaws between the ages of 18 months and 7 years. The swelling progresses rapidly over the next 2–3 years, after which it slows until puberty. Depending on the severity, the swelling can range from little more than broadening of the lower jaw to marked fullness of the lower face associated with thickening of the maxilla. In the most severe cases, maxillary expansion pushes the floor of the orbit upward. The cherubic look results from the combination of the displaced orbit and poorly supported lower eyelid; the altered facial contour permits the rim of sclera to be exposed above the lower eyelid (142). It is uncommon.

Maxillary involvement occurs only when mandibular involvement is severe. When present, it may be viewed

intraorally. The alveolar processes may become thickened and the vault of the palate obliterated to the extent that speech is impaired. Dental abnormalities including delayed eruption, missing or displaced teeth, premature loss of deciduous teeth, and absence of permanent molars have been observed. Enlargement of submandibular lymph nodes has also been described frequently. After puberty, there is a gradual normalization of the facial appearance, although in most cases there is some degree of residual enlargement (142). Treatment varies with the degree of involvement and may often not be needed because of the tendency toward spontaneous improvement.

Radiographs of the mandible taken during childhood reveal bilateral symmetrical well-defined multilocular radiolucent areas associated with expansion of bone and cortical thinning (Figure 159-6) (144,145). The mandibular rami are always involved. The entire mandible may become involved except for the condyles, which are always spared (143). Similar changes are seen in the maxilla when it is affected. The maxillary sinuses may be obliterated. In adults, the radiolucent areas fill in with granular bone and become dense and sclerotic. The radiographic changes of the young are pathognomonic, but those seen in adults are not.

Histologically, the bone is replaced by cellular fibrous tissue containing scattered trabecula of woven bone and many collections of giant cells that resemble osteoclasts. Interestingly, the bone affected by the pathologic process is derived from the first branchial arch.

**FIGURE 159-6** Lateral radiograph of the jaw showing the multilocular lesions of the mandible in an 8-year-old girl with cherubism.

Cherubism is an autosomal dominant trait. A review of 21 families showed that the penetrance is 100% in males and 50–70% in females (146). There is considerable variability, however, and radiographs may be needed to detect mildly affected individuals, especially during adulthood. A few patients have been reported with both cherubism and Noonan syndrome (147–149). The cherubism locus maps to chromosome 4p16.3 (Mangion et al., 1999; Tiziani et al., 1999). Mutations have been detected in a gene that encodes the adapter protein SH3BP2 (7,150,151). Mouse modeling of cherubism has revealed that the mutations cause gain of SH3BP2 function, which promotes inflammatory bone loss mediated substantially through tumor necrosis factor alpha (152).

### Biography

Dr Horton received AB and MD degrees from the University of Kansas, and completed a residency in Internal Medicine at the University of Kansas School of Medicine and fellowship training in Medical Genetics at UCLA-Harbor General Hospital with additional genetics training at the NIH. He has held faculty positions at the University of Kansas School of Medicine, University of Texas Medical School-Houston and Oregon Health & Science University in Portland, where he has also been Director of the Shriners Hospital for Children Research Center since 1993. He has a long-standing research interest in skeletal biology with special emphasis on inherited skeletal dysplasias and their molecular pathogenesis. He has published well over 150 articles and book chapters on both the clinical and basic science aspects of these conditions. He is active in many relevant medical and scientific organizations, sits on a number of advisory and review committees and is considered an expert in the field of skeletal dysplasias.

## The Dysostoses

Deborah Krakow

### 160.1 INTRODUCTION

The dysostoses constitute a group of disorders in which the skeletal involvement is predominantly manifested as abnormalities of individual bones or in a group of bones. These abnormalities can occur singly or in combinations, and frequently occur with other congenital anomalies. They differ from the osteochondrodysplasias, in which there is a generalized abnormality in bone or cartilage, though there can be significant overlap between the dysostoses and the skeletal dysplasias, and among the individual dysostoses. Thus, many of the dysostoses are classified within the *Nosology and Classification of Genetic Skeletal Disorders* (1). The classification of dysostoses can be challenging, though now with increasing knowledge regarding the molecular pathogenesis of these disorders. Unlike the osteochondrodysplasias, the dysostoses have not been officially classified into specific groups. Therefore, a discussion of dysostoses is a description of the specific conditions in which abnormalities of individual bones are seen. Thus, the dysostoses can be grouped into categories of those primarily concerned with craniofacial involvement, those with predominantly axial involvement, and those affecting only the extremities. These categories are purely arbitrary for the convenience of discussion and clinical categorization and do not necessarily reflect underlying or overlapping pathogenesis.

The dysostoses with craniofacial involvement are discussed elsewhere. The well-described dysostoses with predominantly axial involvement or appendicular involvement are included here, though by no means is this list inclusive of all the dysostoses. With the increase in the number of newly described genetic and dysmorphic disorders, there are many new syndromes that have dysostoses as part of the constellation of findings. Many excellent textbooks on syndromes include detailed discussions on dysostoses (2–12).

The dysostoses include conditions in which there is an abnormality in a bone or group of bones. Limb and skeletal patterning and development occur before the 8th week of gestation; consequently, the predominant features of most dysostoses have been determined early in development. Therefore, early developmentally expressed genes

remain excellent candidate genes for these disorders. In many cases, anomalies determined early in gestation can be visualized by prenatal ultrasound; therefore, genetic counseling and prenatal diagnosis should be offered for those disorders with a recurrence risk based on autosomal recessive inheritance or germ line mosaicism.

### 160.2 DYSOSTOSES WITH PREDOMINANTLY AXIAL INVOLVEMENT

#### 160.2.1 Vertebral Segmentation Defects, Including The Klippel–Feil Anomaly (Klippel–Feil Sequence)

Abnormal segmentation can involve any of the vertebral bodies (Figure 160-1) but is most frequently seen in the cervical area (Figure 160-2). Cervical vertebral segmentation anomalies are referred to as the Klippel–Feil anomaly (Klippel–Feil sequence; Online Mendelian Inheritance in Man (OMIM) 148900) whether they involve fusion of two segments or the entire cervical spine. There are actually several distinct subcategories, as originally defined by Gunderson et al. (13). Dominant inheritance, recessive inheritance, and no simple genetic basis for the disorder are all possible. The mechanism that leads to the malformations seen in the Klippel–Feil anomaly appears to be a failure of the normal segmentation and fusion processes of the mesodermal somites, which occurs between the 3rd and 7th weeks of gestation. Bouwes Bavinck and Weaver (14) have proposed that this occurs on the basis of a vascular accident early in development, although there is disagreement on this hypothesis. Familial cases have been reported (15), though the vast majority of cases occur sporadically, or as part of other genetic syndromes.

Clinically, Klippel–Feil syndrome consists of a triad: (1) short neck, often with the presence of pterygium colli; (2) low hairline; and (3) painless limitation of head movement. The scapula is frequently displaced. Neurologic compromise is occasionally present, and it may imply that the spinal cord has been compressed or that there is a congenital structural anomaly of the spinal cord. The most severe form of cervical segmentation defect is discussed

under spondylocostal dysplasia. Hemivertebrae, defective posterior elements (spina bifida occulta), clefting of the vertebral body anteriorly, reduction in the number of vertebrae, and anomalies at the occipital-atlantal articulation may be seen (4). Segmentation abnormalities in the C2–3 region may lead to subluxation and secondary cord compression. Patients with the Klippel–Feil anomaly should have flexion/extension radiographs to evaluate the cervical vertebrae. Subluxation of the thoracic or lumbar vertebrae can also occur, leading to spinal nerve compression. Abnormal segmentation in the thoracic and lumbar areas leads to scoliosis, either congenitally or developing during early childhood. In addition to the vertebral anomalies, extra, fused, or missing ribs and Sprengel anomaly (upward displacement of the scapula) are often seen.

Other congenital anomalies may be seen frequently with multiple vertebral fusion defects. Congenital heart disease, vascular abnormalities, and cleft palates may be present. Hearing loss (80%) with structural anomalies of the ossicles (16), renal dysgenesis ranging from hypoplasia to bilateral agenesis, internal genital anomalies including vaginal atresia and bicornuate uterus, limb anomalies, partial facial paralysis, and ptosis have also been reported (13,17).

In 1967, Gunderson et al. distinguished three types of cervical vertebral fusion defect (13):

- Type I—massive fusion of many cervical and upper thoracic vertebrae into bony blocks (Figures 160-1 and 160-2)
- Type II—fusions of only one or two interspaces, usually C2–3 or C5–6; however, there can be intrafamilial variability, hemivertebrae and occipital-atlantal fusion, and other congenital anomalies
- Type III—multiple vertebral segmentation anomaly, including both cervical fusion and lower thoracic or lumbar fusion

A fourth type of Klippel–Feil anomaly has been suggested and is associated with sacral agenesis (18). This attempt to sort out familial types of vertebral fusion and the presence or absence of other system involvement is very helpful, though not all cases fit the classification.

In type I, most reported cases are sporadic, and may have multiple other congenital anomalies. There are isolated case reports of a second affected sib or a sib with multiple congenital anomalies, raising the possibility of a rare recessive gene or somatic mosaicism being responsible for the anomalies (19). In type II, other congenital anomalies are rarely noted; type III is often associated with multiple organ anomalies and subsequent neurologic compromise. Usually, it is a sporadic occurrence in the family. However, Wynne-Davies (19) recognized families with an apparent autosomal dominant inheritance with marked variability in vertebral anomalies. Clarke et al. (15) described a four-generation Klippel–Feil syndrome family with an autosomal dominant form of the disorder. The vertebral fusion was confined to the cervical spine and

**FIGURE 160-1** Klippel–Feil anomaly. Radiograph of the thoracic spine. Note right sixth thoracic hemivertebrae, and associated changes in T5.

**FIGURE 160-2** Klippel–Feil anomaly. Radiograph of cervical spine. Note the fusion of the posterior elements of C1 to the occiput and fusion and partial rotation of C2–5.

occurred in association with malformation of laryngeal cartilages, mild to severe vocal impairment, and microtia. Some members of the family had a history of mild conductive hearing impairment and bilateral restricted supination and limited flexion of the elbow. The syndrome co-segregated with a pericentric inversion on chromosome 8, inv(q22.2.q22.3), and demonstrated a mutation in the gene that encodes growth and differentiation factor 6 (*GDF6*) produces the phenotype (15b). Some other sporadic cases also had mutations in *GDF6*, though these changes account for a small number of affected individuals with Klippel–Feil disorder. Further, Ye et al. in 2010 identified two individuals from one family with isolated Klippel–Feil abnormality and heterozygosity for mutations in *GDF3* (20). Though this represents a limited number of cases in which the molecular basis of Klippel–Feil has been isolated, the findings demonstrate the importance of alterations in BMP signaling affecting the cervical spine.

A subdivision of vertebral segmentation anomalies has been designated the Wildervanck or cervical-oculoacoustic syndrome (OMIM 314600), in which there is a preponderance of females (21). It is characterized by congenital perceptive deafness, abducens paralysis with retraction of the bulb of one or both eyes (Duane syndrome), facial hypoplasia and asymmetry, fusion of cervical vertebrae, and occasionally elbow hypoplasia.

Both the MURCS (OMIM 601076) and VATER (OMIM 192350) associations have vertebral anomalies with multiple other congenital abnormalities that occur together more frequently than would be expected by chance (8). The MURCS association consists of müllerian duct aplasia; renal hypoplasia, dysgenesis, or ectopia; and cervical-thoracic somite dysplasia. The VATER association consists of vertebral anomalies, anal anomalies, and tracheal, esophageal, and radial ray defects. The original observations—renal, cardiac, and limb anomalies and single umbilical artery—were also noted to be seen with this group, giving rise to the acronym VACTERLS. Therefore, some cases with Klippel–Feil anomaly may have the aforementioned associations, and consideration should be given to screening those patients for other congenital anomalies. Recent advances in genome analysis may uncover the underlying mechanism of these disorders and it is possible that these associations are genetically complex in their origin.

The pathogenesis of isolated Klippel–Feil is not well understood. This probably results from genetic and allelic heterogeneity, and in some cases, contributing nongenetic causes. PAX1, a developmentally expressed transcription factor, has been implicated as a possible candidate gene (22). The mouse *Pax1* mutant phenotype “undulated” shows vertebral segmentation defects similar to human Klippel–Feil syndrome (23). Analysis of a cohort of individuals with Klippel–Feil syndrome identified some sequence changes not seen in control patients, suggesting an association with the disorder, but no conclusive data implicated PAX1 as causative. As mentioned above, some cases of Klippel–Feil result from heterozygosity for changes in the gene that encodes GDF6 and GDF3.

### 160.2.2 Spondylocostal and Spondylothoracic Dysostoses

There are several types of spondylocostal and spondylothoracic dysostoses (OMIM 277300; OMIM 608681), in which abnormal spinal segmentation and malformations of the ribs occur. Spondylocostal dysostoses (SCDOs) show considerable clinical and radiographic overlap with spondylothoracic dysostoses. Usage of varying terms to describe vertebral segmentation disorders that include costovertebral/spondylocostal/spondylothoracic dysostosis/dysplasia has led to significant confusion in the literature. Further, there are some cases that defy classification. Clinically, these patients have a short neck and/or trunk.

Other visceral malformations are not generally seen, though when seen, they frequently correspond to the site of the vertebral segmentation defects (24). This group of dysostoses falls into two major types: (1) mild varieties, which may be inherited as a dominant condition (SCDO type 5); and (2) more severe varieties, which may be inherited as autosomal recessive traits and the types are now based on gene identification (SCDO types 1–4) (23a–30).

Dominantly inherited multiple segmentation anomalies of vertebrae (SCDO5) are characterized by hemivertebrae, fused vertebrae, butterfly vertebrae, and various rib anomalies, and the genetic etiology remains unknown (19,31). Because of marked variability within these families, detailed radiographs are needed to establish the possibility of subclinical hemivertebrae or fusion. Individuals with the recessively inherited types of multiple segmentation anomalies of the vertebrae have marked shortening of the trunks, and diagnosis is readily apparent because the disproportion of the short trunk is dramatic when compared with the relatively long limbs. However, there appear to be several forms and genetic heterogeneity has been established. In the Jarcho–Levin spondylothoracic dysostoses (occipito-facial-cervicothoracic-abdomino-digital dysplasia, described in 1938), the severe disproportion of the trunk and limbs gives a crablike appearance on radiographs, resulting from marked platyspondylia of the fused vertebrae (32). Many of these children succumb secondary to respiratory difficulties. Jarcho–Levin syndrome is more frequently seen in individuals of Puerto Rican ancestry and the eponym is used when the disorder manifests in Puerto Rican individuals of Spanish descent (33). The gene responsible for Jarcho–Levin in the Puerto Rican population is *MESP2*. A homozygous nonsense mutation is responsible for approximately 80% of spondylothoracic dysostosis cases in the Puerto Rican population, suggesting a founder effect (33a). In mouse models, *Mesp2* has been shown to be expressed in presomitic mesoderm and plays a critical role in vertebral body formation (33b). Recessively inherited mutations in *MESP2* that occur in individuals of non-Puerto-Rican inheritance produce spondylocostal dysostoses of type 2 (SCDO2) (33a).

There are other identified genes that produce autosomal recessive SCDOs (34). Using homology of synteny (the “pudgy” mouse) and linkage analysis, the gene for SCDO1 was identified as *DLL3*, or delta-like-3 gene (35). *DLL3* is a notch ligand, therefore revealing the role of the notch-signaling pathway in patterning of the human skeleton. Mutations in lunatic fringe (*LFNG*) lead to SCDO3, and *HES7* produces SCDO4 (36). *MESP2*, *DLL3*, *LFNG*, and *HES7* are all components in notch signaling, demonstrating the importance of notch signaling in axial skeletal development. However, the gene defect has not been established in all cases of spondylocostal and spondylothoracic dysostoses. Within this group of disorders, there is significant phenotypic and genetic heterogeneity.

### 160.2.3 Sprengel Deformity

Sprengel deformity (Sprengel sequence; OMIM 184400) is characterized by a congenital upward displacement of the scapula. It usually occurs as a sporadic event (unilateral or bilateral) or in association with a variety of abnormalities. Most cases of Sprengel deformity are sporadic; however, a few families have been described with autosomal dominant transmission (37,38). Sprengel deformity presumably results from a failure of the normal embryologic descent of the scapula from the neck to the thorax during the second month of gestation.

The scapula is usually hypoplastic and abnormal in shape. As a result of its abnormal shape and position, it may produce a lump in the upper back and lead to restricted movement of the shoulder. In 20–50% of cases, there is accumulation of connective tissue or even bony fusion between the scapula and ribs or vertebrae (39). Associated skeletal anomalies occur in more than half of cases, and Sprengel deformity can be seen in Klippel-Feil syndrome. Scoliosis, hemivertebrae, fused vertebrae, spina bifida occulta, cervical ribs, missing ribs, fused ribs, clavicular anomalies, and hypoplasia of the muscles of the shoulder girdle can also co-segregate with Sprengel deformity. Association with situs inversus has been described, as have chest deformities and limb anomalies (40). Many cases of Sprengel deformity seem to be only one manifestation of a more generalized disturbance of the shoulder girdle and upper thorax (11). Surgery may be needed, both to improve function of the shoulder and back and to improve cosmetic appearance. Surgery usually involves removal of the scapulovertebral communication. Without surgery, exercise and stretching seem to be of little value.

### 160.2.4 Osteo-Onychodysostosis (Nail-Patella Syndrome)

Osteo-onychodysostosis (OMIM 161200) is a dominantly inherited condition with four major clinical features: dysplasia of the nails, absence or hypoplasia of the patella (Figure 160-3), abnormalities of the elbow, and the presence of iliac horns (pyramidal spurs just outside the sacroiliac line) (Figure 160-4). The tendency to develop nephritis can be a serious complication and seems to have a familial aggregation (6).

The disorder is recognized at different ages, depending on the degree of involvement (41). Some patients have difficulty walking because of instability of the knee. Occasionally, infants present with contractures of hips, knees, elbows, feet, or fingers and may even have pterygium across the joints. Other individuals are basically asymptomatic and only recognized as a part of family studies. Height is usually within normal limits, but affected individuals are mildly short for the family.

The nails are abnormal, and the thumb and index fingers are most often affected. They may be small and concave,

**FIGURE 160-3** Nail-patella syndrome (osteonychodysostosis). Radiograph of the knee. Note absent patella and proximal tibial distortion.

**FIGURE 160-4** Nail-patella syndrome (osteonychodysostosis). Radiograph of the pelvis. Note flaring of the iliac wings with definitive iliac horns.

longitudinally grooved, abnormally split, pitted, softened, discolored, or brittle with triangular-shaped lacuna or central hypoplasia. The toes are rarely involved. The patellae are absent or small and laterally dislocated and may be bipartite (Figure 160-3). They may subluxate or dislocate. Prominence of the medial femoral condyle, hypoplasia of the lateral femoral condyle, and proximal tibia distortion are all seen. Hypoplasia of knee tendons and hypoplasia of the quadriceps and vastus medialis may contribute to instability of the knee. At the elbow, hypoplasia of the capitulum and relative hypertrophy of the medial condyle with hypoplasia of the radial head are present. Lateral or posterior subluxation of the radial head results in decreased pronation/supination and lack of full extension. Webbing at

the elbow may be seen, and the carrying angle is increased. Deltoid, triceps, and brachioradialis hypoplasia occur (4). Hypoplasia of the lateral humeral condyle and head of the fibula may also be seen. Iliac horns arising from the central area of the outer surface of the iliac wing are usually pyramidal in shape and are diagnostic of this disorder (Figure 160-4). The iliac horns occur bilaterally but may be asymmetrical. They are palpable in many patients, but they are rarely clinically relevant. Other reported skeletal anomalies include foot changes (equinovarus, calcaneovalgus, or most frequently, pes planus), dislocated hips, coxa valgus, and contractures of other major joints. Another significant abnormality in nail–patella syndrome is the presence of open-angle glaucoma (42).

The renal lesion in nail–patella syndrome resembles chronic glomerulonephritis without infection (3). Clinically, the renal involvement presents with proteinuria. Uremia develops in 30% of patients. Accumulation of abnormal collagen fibers and thickening of the basement membrane can be found in the glomeruli on autopsy. Taguchi et al. (43) demonstrated the characteristic changes in the glomeruli in nail–patella syndrome patients without clinical renal involvement. These changes may represent a basic structural defect present as part of the disease, rather than a phenomenon that is secondary to glomerular sclerosis (44). All patients should be screened for renal disease, especially those in families with a history of renal involvement.

The gene localization for nail–patella syndrome had been known since 1976, when it was linked to the ABO blood group on chromosome 9q34. The location of the gene was reduced to a small chromosomal interval (45), and the gene defect identified in *LMX1B*, a LIM-homeodomain transcription factor (46). The majority of mutations in *LMX1B* are premature stop codons, resulting in haploinsufficiency for *LMX1B*. *LMX1B* plays a critical role in dorsal/ventral patterning of the vertebral limb. Targeted disruption of *Lmx1b* in mice produces a phenotype similar to that seen in humans, including absence of the nails and patella, as well as abnormal renal pathology (47).

Differential diagnosis for nail–patella syndrome consists of syndromes associated with absent/small patella and nail changes. These include small patella syndrome (OMIM 147891), patella aplasia-hypoplasia (OMIM 168860), familial recurrent dislocation patella (OMIM 169000), Meier–Gorlin syndrome (OMIM 224690), genitopatellar syndrome (OMIM 606170), DOOR syndrome (deafness, onychodystrophy, osteodystrophy, mental retardation; OMIM 220500), Coffin–Siris syndrome (OMIM 135900), and RAPADILINO syndrome (radial ray defect, patellar hypoplasia, diarrhea and dislocated joints, limb malformations, long slender nose and normal intelligence; OMIM 255280). Senior syndrome (OMIM 113477) and ectodermal dysplasias have similar nail abnormalities but also have skin changes that are distinct and not seen in nail–patella syndrome.

### 160.2.5 Cerebrocostomandibular Syndrome (Rib Gap)

Rib gaps (consisting of uncalcified fibrous or cartilaginous tissues in the posterior part of the rib causing “flail chest”), Pierre–Robin anomaly (micrognathia, cleft palate, glossoptosis), and vertebral dysplasia are the constellation of findings in this syndrome (OMIM 117650). Abnormalities of the heart and brain, extra skin at the neck, collapsing trachea, deafness, mental retardation, hydrocephaly, spina bifida, subluxation of the elbows, and polycystic kidneys have also been reported (48,49). There can be marked variability of expression within families.

In infancy, radiographic gaps in the dorsal portions of the ribs with fragmented ossification and absence of normal costovertebral articulations are seen. Lesions are bilateral but not necessarily symmetrical. Most affected infants die in the newborn period of respiratory insufficiency due to a flail chest. Frequently, affected individuals fail to thrive, and many have feeding problems because of the micrognathia and may require feeding gastrostomy.

Both autosomal dominant ((50), Morin et al., 2001a) and autosomal recessive inheritance have been reported, though the recessive inheritance pattern may represent germ line mosaicism. Zeevaert et al., 2009 (50b) reported homozygosity for mutations in *COG1* (component of oligomeric Golgi complex 1) in two patients with a cerebrocostomandibular-like syndrome, but additional patients with cerebrocostomandibular syndrome (CCMS) mutations were not identified. Rib gaps may be seen in several conditions (e.g. diaphanospondylodysostosis; OMIM 608022) and are thus not pathognomonic for the diagnosis of CCMS.

## 160.3 PREDOMINANT LIMB INVOLVEMENT

### 160.3.1 Acheiropodia

Acheiropodia (absence of the hands and feet; OMIM 200500) is an autosomal recessively inherited condition with absence anomalies of both upper and lower limbs, usually with symmetrical involvement. Acheiropodia has only been seen in inbred Brazilian kindreds of Portuguese origin (51,52). The limb malformation involves a terminal transverse hemimelia (below the elbow) in the upper limbs and a terminal transverse hemimelia of the distal third of the lower limbs. Some affected individuals have an elongated small bone at the tip of the stump (Bohomoletz bone) parallel to the humerus. This inherited condition can be differentiated from other terminal transverse hemimelia conditions in that the latter usually have unilateral involvement of the upper limbs and the lower limbs are rarely involved, whereas the defects in acheiropodia are usually uniform and bilateral and involve both upper and lower limbs (53). In addition, there are no other associated abnormalities in acheiropodia. The chromosomal

location of the gene defect, chromosome 7q36, was established (54), and the disease gene identified: *C7ORF2*, the human homolog of the *Lmbr1* gene (55). The differential diagnoses for acheiropodia include thalidomide syndrome, amniotic bands, and Hanhart syndrome.

### 160.3.2 Tetraphocomelia–Cleft Palate Syndrome (Roberts Syndrome, Pseudothalidomide Syndrome, SC Syndrome)

This is a striking syndrome with autosomal recessive inheritance (OMIM 268300). Limb reduction anomalies are seen in all four extremities. The limb abnormalities include shortening, fusion, or absence of the long bones (tetraphocomelia), often with reduction in the number of fingers and occasionally toes (missing or fused metacarpals or phalanges). These dysostoses are seen together with cleft lip and palate (usually bilateral, but occasionally only cleft palate or high palate). Midline facial hemangioma, mental retardation, intrauterine growth retardation, ocular hypertelorism, hypoplastic alae nasi, cloudy cornea, and fine thin silvery-blond hair are often present. Occasionally, relatively large clitoris or penis, cystic renal changes, or central nervous system structural changes (encephalocele, hydrocephaly) are seen (56,57).

Chromosome studies show puffing and premature separation of the centromeres in the heterochromatic C-banded regions of most chromosomes, but particularly chromosomes 1, 9, 16, and Y (58). It has been demonstrated that some Roberts syndrome patients have an abnormality in constitutive heterochromatin and show cellular hypersensitivity to DNA-damaging agents such as mitomycin C. Roberts syndrome results from mutations in the *ESCO2* gene (59), the protein product of which is required for the establishment of sister chromatid cohesion during S phase.

### 160.3.3 Oro-acral Syndrome (Hanhart Syndrome, Aglossia Adactylia, Ankyloglossia Superior)

Limb reduction (usually all four limbs with transverse amputations) and intraoral anomalies (usually a small or vestigial tongue, sometimes with adhesions of the tongue to the hard palate) comprise a distinctive syndrome that appears to be sporadic (OMIM 103300) (60). The etiology is unknown.

The mandible is usually severely micrognathic (61), which can lead to feeding abnormalities. Although the tongue may be rudimentary, speech is usually possible. The lower incisors may be absent, and occasionally bony adhesions of the jaw and cleft palate occur. The type of limb defect varies from just absent digits to complete transverse absence below the elbow and knee (62). The humerus and femur are always preserved, and lower limbs are usually spared when compared with the upper limbs (4,63,64). There is never complete lack of either

tongue or limbs. Intelligence is usually normal. Occasionally, Möbius syndrome (OMIM 157500) is seen in association with oro-acral syndrome (12).

### 160.3.4 Radioulnar and Humeroradial Synostoses

Radioulnar and humeroradial synostosis (bony fusion at the elbow joint; OMIM 179300; OMIM 143050) can occur as an isolated anomaly or in association with several specific syndromes. Early in life, there may appear to be a joint space on radiographs, but cartilaginous synostosis may already have occurred.

In isolated radioulnar synostosis, a proximal bony fusion of the radius and ulna is seen radiographically, and there is impaired pronation/supination of the arm. Consequent limitation of function is usually minimal. Several families have been reported with dominant inheritance (65). Radioulnar synostosis is also seen in several chromosomal disorders, particularly involving abnormal numbers of X and Y chromosomes (e.g. 47,XXX). In addition, radioulnar synostosis can be seen in Poland syndrome, SC or pseudothalidomide syndrome, Pfeiffer syndrome, and Permian syndrome.

Clinically, patients with humeroradial synostosis have an immobile elbow joint with decreased muscle in the upper arm, and bony fusion is seen on radiographic examination. Surgical manipulation may be necessary to improve function. Isolated humeroradial synostosis can be inherited as an autosomal recessive trait (Keutel et al., 1970) or as a dominant (66), or frequently as a sporadic occurrence. Of note, humeroradial synostosis is often a component of multiple synostosis and other genetic syndromes.

### 160.3.5 Brachydactyly

Brachydactyly, or shortening of the digits due to abnormal development of either the phalanges or metacarpals, is seen either as an isolated malformation (in a variety of different forms) or in conjunction with anomalies of one or more other systems (67). Bell classified the isolated brachydactylies into 10 definitive groups (A1–6, B, C, D, and E) (Table 160-1) on the basis of her review of 1336 individuals affected with brachydactyly. Familial reports of each type of isolated brachydactyly have shown an autosomal dominant pattern of inheritance.

Brachydactyly A is also called brachymesophalangia because there is a shortening of the middle phalanges. In brachydactyly type A1 (Farabee type, BDA1; OMIM 112500), all middle phalanges are short or hypoplastic, and the proximal phalanges of the thumbs and halluces may be shortened. In the most severe cases, fingers are approximately one-half their normal length. The third digit is usually least affected. Severe cases may have both cosmetic and functional problems. In two large families with BDA1, the gene has been mapped to chromosome

**TABLE 160-1** Listing of Brachydactyly Syndromes and Responsible Genes

Brachydactyly Type (BD)	Gene(s)
A1 (BDA1)	Indian hedgehog ( <i>IHH</i> )
A2 (BDA2)	Bone morphogenetic protein receptor 1B ( <i>BMPR1B</i> )
A3 (BDA3)	Unknown
A4 (BDA4)	Unknown
A5 (BDA5)	Unknown
A6 (BDA6)	Unknown
B (BDB1)	<i>ROR2</i>
C (BDC)	<i>GDF5</i>
D (BDD)	<i>HOXD13</i>
E (BDE)	<i>HOXD13</i>

2q35–36 (20a). Gao et al. (61a) showed that heterozygosity for mutations in the Indian hedgehog (*IHH*) gene were responsible for the disorder. Indian hedgehog belongs a family of conserved genes involved in signaling. Another locus for BDA1 (*BDA1B*) has been identified on chromosome 5p13.2 (68), and the possibility of a third locus has been suggested (69).

In brachydactyly type A2 (BDA2; OMIM 112600), the middle phalanges are shortened; however, the shortening is predominantly in the second digits. The middle phalanx has a characteristic rhomboid or triangular shape as a result of a continuous epiphysis from proximal to distal ends on the shortened side. Consequently, growth of the phalanx is outward and results in radial angulation. Heterozygosity for mutations in the bone morphogenetic protein receptor 1B gene (*BMPR1B*) and growth and differentiation factor 5 (*GDF5*) leads to BDA2 (70,70a). Further, alterations (deletions or duplications) in the gene for bone morphogenetic protein 2, *BMP2*, lead to BDA2 (70c,d). Type A3 (BDA3; OMIM 112700) is characterized by shortening of the middle phalanx of the fifth finger. The epiphyses may be cone shaped, and there is usually radial curving of the little finger, resulting in clinodactyly. It is seen with increased frequency in individuals of Asian descent (71). In type A4 (BDA4; OMIM 112800), the middle phalanges of digits 2 and 5 are shortened. If digit 4 is affected, there is radial deviation. Clubfoot can be seen in these families. Finally, type A5 has shortening of all middle phalanges but is also associated with nail dysplasia and bifid distal phalanges of the thumb and hallux (72). Brachydactyly A5 can be confused with brachydactyly B; however, the latter is distinguished by hypoplasia of the distal phalanges, according to Temtamy and McKusick (10). Brachydactyly A5 has not been reported as a distinct entity in the literature. Osebold et al. (73) reported a sixth form of brachymesophalangia (BDA6; OMIM 112910) with mesomelic shortening of the limbs and radial deviation of the index finger, though it has been suggested that the findings in this family represented a form of chondrodysplasia punctata (74).

In brachydactyly type B (BDB1; OMIM 113000), the first brachydactyly to be described in the literature (69a), there is shortening of middle phalanges and shortening or complete absence of the terminal phalanges. Digits on the radial side of the hand are usually less severely affected than digits on the ulnar side (10). Abnormalities are consistently symmetrical, and the feet are less severely affected. Soft tissue syndactyly, symphalangism, carpal and tarsal fusions, and shortening of metacarpals and metatarsals may be additional features. The additional abnormalities can be severely debilitating. A distinctive facies has been associated with BDB1, including wide-spaced, down-slanting palpebral fissures and a bulbous nose (75). Some authors have referred to brachydactyly B as symbrachydactyly or apical atrophy because of the syndactyly, fusion of phalanges, and lack of terminal phalanges. Heterozygosity for mutations in the receptor tyrosine kinase-like orphan receptor gene, *ROR2*, is responsible for BDB1 (76). Mice homozygous for the defects in *Ror2* were found to have abnormal patterning of the digits, similar to those seen in BDB1 (77).

Brachydactyly type C (BDC; OMIM 113100) has marked variability. However, characteristically, the middle and proximal phalanges of digit 5 are shortened, although anomalies also occur in the index and middle fingers. It is striking that the fourth digit is basically normal and extends beyond the other digits. There may be marked ulnar deviation of the proximal phalanx of the index finger. Short metacarpals and symphalangism are occasionally seen, and there may be bifid phalanges and/or radial projections. There is only minimal involvement of the feet. Short stature and clubfeet may be associated features. Radiographic studies show delayed maturation of ossification centers and hypoplasia, aplasia, or early fusion of the epiphyses (10). BDC results from heterozygosity for mutations in the growth differentiation factor V gene (*GDF5*) or *CDMP1*, a member of the bone morphogenetic proteins (78). While genetic heterogeneity has been suggested in BDC, in a large family that showed linkage to chromosome 12q24 (79), it was demonstrated that the disease was produced by heterozygosity for an insertion in *GDF5* (80).

Brachydactyly type D (BDD; OMIM 113200) is characterized by a shortened, broad terminal phalanx of the thumbs and great toes, usually expressed bilaterally. The abnormality is attributed to an early closure of the epiphysis at the base of the distal phalanx of the thumb (10). Reynolds et al. (81) reported the familial association of BDD and Hirschsprung disease. Gray and Hurt (82) found incomplete penetrance in males but complete penetrance in females. In at least some individuals with BDD, heterozygosity for mutations in *HOXD13* have been identified, though the affected individuals had an overlap phenotype between BDD and BDE (83).

Finally, brachydactyly type E (BDE; OMIM 113300) is characterized by shortening of one of or all the metacarpals or metatarsals. Terminal phalanges are often short,

and hyperextensibility of the hands is common. The fourth digit is most frequently affected. There may be associated mild short stature (84) or mild generalized spondyloepiphyseal changes (85). Families with BDE associated with one of the following features have been reported: microcornea, keratoconus, and hypertension. BDE with short stature and hypertension has been mapped to chromosome 12p12.2–p11.2 (86). As noted earlier, individuals with an overlap BDD/BDE phenotype have been shown to be heterozygous for *HOXD13* mutations.

### 160.3.6 Symphalangism

Symphalangism, or fusion of the phalanges, can be seen as an isolated finding (often post-traumatically) or inherited as an autosomal dominant trait. Both proximal (87) and distal (88) forms have been described. Families with distal symphalangism are rare, whereas proximal symphalangism is a much more common phenomenon. In addition, distal symphalangism tends to be an isolated anomaly and proximal symphalangism tends to occur with other associated abnormalities.

In dominantly inherited proximal symphalangism (OMIM 185800), usually more than one joint or finger is involved (Figures 160-5 and 160-6), but variability in the age of onset and severity is seen within families. Involvement of other bones can be seen, such as coalition or fusion of the tarsal and carpal bones, radial head dislocation, radiohumeral synostosis, vertebral synostosis, scoliosis, craniosynostosis, and deafness in affected family members. Therefore, careful evaluation of all joints, spine, and skull and hearing should be performed in family members of a patient affected with symphalangism. Symphalangism may be present at birth; however, radiographic examination at birth may not show complete bony fusion but simply a narrowing of the interzone. In contrast to other types of contractures and dysostotic processes, individuals with symphalangism may actually be made worse (i.e. have more rapid fusion) by vigorous physical therapy.

Multiple synostoses syndrome (OMIM 186500), considered a distinct syndrome from proximal symphalangism, has many overlapping features. In multiple synostoses syndrome, the symphalangism follows a pattern similar to proximal symphalangism, but is usually more extensive. Several kindreds with autosomal dominantly inherited proximal symphalangism and multiple synostosis syndromes have conductive deafness, with onset usually at the age of 2 or 3 years and progression throughout childhood. A bony fusion of the stapes and petrous part of the temporal bone has been demonstrated at surgery in several patients. In multiple synostosis families, affected individuals tend to have long, narrow faces and a prominent nose with a broad bridge and hypoplastic alae nasi. Fingers can be short and may even be missing the distal phalanx and nail.

Whether proximal symphalangism and multiple synostosis syndromes are allelic has been a long-standing

question. Linkage analysis in both proximal symphalangism (89) and multiple synostoses syndrome (89a) mapped both disorders to the identical chromosomal location, 17q21–22. In both of these disorders, heterozygosity for mutations in the *NOGGIN* gene was demonstrated (89b,90). *NOGGIN* is a developmentally expressed gene that is a regulator of the bone morphogenic proteins (3a) that are involved in chondrogenesis. *Noggin* null mutant mice fail to initiate normal joint development and exhibit extensive cartilaginous fusions. Further mutations in *GDF5* and *FGF9* also produce multiple synostoses syndrome, implicating both BMP and FGF signaling in the formation and maintenance of joints.

### 160.3.7 Polydactyly

Patients with polydactyly, or the presence of a supernumerary digit or a portion of an extra digit(s), can be classified into two major groups: those with preaxial addition and those with postaxial addition (4,91).

Isolated postaxial polydactyly has long been recognized as a specific entity, is more common in some populations, and is inherited as a dominant trait. In the same family with apparent dominant inheritance, variability of expression can be so marked that the gene is clinically manifested as fully developed extra digits (type A1; OMIM 174200) in some family members and simply as rudimentary supernumerary digits or postminimi (type B; OMIM 174200) in others (10). In an Indian family with type A polydactyly, Radhakrishna et al. (92) identified heterozygosity for a mutation in *GLI3*, one of the vertebrate orthologs of the *Drosophila* cubitus interruptus gene. This expands the phenotype of *GLI3* mutations from Greig cephalopolydactyly syndrome to Pallister–Hall syndrome to isolated postaxial polydactyly types A1 and B. Postminimi can be removed at birth by occluding the skin tag with a tight thread or string; the tag subsequently drops off. Adults so treated may often be unaware that they had polydactyly, and a careful family history should therefore be taken from parents. By contrast, extra digits involving bone or cartilage must be excised surgically to avoid osteomyelitis.

Preaxial polydactyly is much less common than postaxial polydactyly and has been subdivided into four different categories by Temtamy and McKusick (10):

- Type 1—preaxial thumb polydactyly (OMIM 174400)
- Type 2—polydactyly of a triphalangeal thumb (OMIM 174500); linkage has been established to chromosome 7q36 (93) and has been shown to be due to point mutations in a sonic hedgehog (*SHH*) gene regulatory element that resides in intron five of *LMBR1* (50a)
- Type 3—polydactyly of an index finger (OMIM 174600)
- Type 4—preaxial polydactyly and syndactyly, or crossed polydactyly type I (OMIM 174700).

**FIGURE 160-5** Proximal symphalangism. Radiograph of the dorsal view of the hands. Note fusion of proximal phalanges on digits 4 and 5 and partial fusion of the proximal phalanges on digits 2 and 3.

**FIGURE 160-6** Proximal symphalangism. Hands are held in tight fist. Note the absence of flexion creases over the proximal phalanges on digits 3, 4, and 5 and the partial function of the proximal joint of digit 1 bilaterally.

Heterozygosity for mutations in *GLI3* has been shown to produce this type of poly- and syndactyly (94). All types are inherited as autosomal dominant traits, but variability and reduced penetrance have been reported (7).

Polydactyly is associated with several specific syndromes, the most notable of which are the chondrodysplasias, such as Ellis–van Creveld (chondroectodermal dysplasia), the acrocephalosyndactylies, hypothalamic hamartoblastoma syndrome (95), Meckel syndrome, trisomies 13 and 18, Laurence–Moon–Biedl syndrome, Biemond syndrome type II, orofaciocigital syndrome types II and III, polydactyly with dental and vertebral anomalies (96,97), syndrome of polydactyly with myopia, polydactyly with imperforate anus and vertebral anomalies

(98), scalp defects and polydactyly (99), Kaufman syndrome, and several chromosomal anomalies. For the specific dysostotic changes found in other bones in these syndromes, consult Taybi and Lachman (9).

### 160.3.8 Syndactyly

Syndactyly, or webbing of the fingers, can be complete or partial; it can be simple, with only skin binding the fingers together, or complicated, when there are fused bones, extra bones, or shared structures, such as nerves, vessels, or nails (4). Isolated syndactyly has at least five forms. All five are inherited as autosomal dominant traits and are usually bilaterally symmetrical. Variability of expression is seen (100).

Syndactyly type 1 (SD1, zygodactyly; OMIM 185900) is a cutaneous fusion of the third and fourth fingers and/or second and third toes. The webbing is usually to the nail base. Occasionally, other digits can be affected. In one large family, the SD1 locus has been identified on chromosome 2q34–q36 (101), as confirmed by Ghadami and colleagues (102).

Syndactyly type 2 (synpolydactyly, central polydactyly, SPD; OMIM 186000) is also complete cutaneous webbing of the third and fourth fingers, with a partially duplicated digit hidden in the web. In the feet, there is syndactyly of the fourth and fifth toes, with a sixth toe in the web. Heterozygosity for mutations in *HOXD13* is responsible for the phenotype (103).

Syndactyly type 3 (ring finger, SDTY; OMIM 186100) is complete cutaneous webbing between the fourth and fifth fingers. The middle phalanx of the fifth fingers may be hypoplastic. The feet are usually normal. Heterozygosity for mutations in the gap junction protein alpha-1 (*GJA1*) gene has been demonstrated (104). This is also the gene responsible for oculodentodigital dysplasia (OMIM 164200).

Syndactyly type 4 (Hass; OMIM 186200) involves syndactyly of all fingers and the thumb, with finger flexion creating a cuplike hand. The feet may have lateral polydactyly. Syndactyly type 5 (MC/MT synostosis; OMIM 186300) involves cutaneous syndactyly of the third and fourth fingers with synostosis of the metacarpals of digits 4 and 5. In the foot, there is syndactyly of toes 2 and 3 and metatarsals 4 and 5. In two families, duplications in limb region 1, mouse, homolog (*LMRB1*) lead to the phenotype (85a,105). These findings implicate an allelic series that includes acheiropodia, olydactyly, preaxial type II, syndactyly, type IV, triphalangeal thumb, type I, and triphalangeal thumb-polysyndactyly syndrome.

Syndactyly can also be seen in an X-linked syndrome of syndactyly with mental retardation. Syndactyly also occurs in Smith–Lemli–Opitz, Apert, Pfeiffer, Carpenter, Saethre–Chotzen, orofacioidigital, Goltz, and multiple pterygium syndromes. The genes for many of these disorders have been identified.

### 160.3.9 Camptodactyly

Camptodactyly is clinically manifested by soft-tissue flexion contractures of the fingers at one or several joints. Contractures may be present at birth or develop in childhood or even adulthood; they may be stationary or progressive or may improve with physical therapy. Camptodactyly may be seen as an isolated anomaly, inherited as an autosomal dominant trait (91,106), or occur as a feature in many syndromes. Camptodactyly does not usually interfere with function unless it is very severe at birth or vigorous physical therapy is not begun early enough.

There are probably several different etiologies of camptodactyly, one of which is misplaced, hypoplastic,

or absent tendons (107,108). The types of contractures seen in camptodactyly often benefit from surgical repair, by reattaching tendons or soft-tissue release, and from physical therapy with stretching exercises (109). Both fingers and toes can be affected. Some forms may represent early aging, inflammatory response, or deterioration of connective tissue, which would lead to fibrosis and contracture of tendons.

Recently, several syndromes that include finger contractures along with many other features have been given a primary designation of camptodactyly, which may be confusing. These include Tel Hashomer camptodactyly syndrome (camptodactyly, distinctive facial features, dermatoglyphic changes, and musculoskeletal anomalies; OMIM 211960), which is inherited in inbred Arab and Brazilian families as an autosomal recessive (110); Guadalajara camptodactyly I (camptodactyly, intrauterine growth retardation, mental retardation, unusual facies, and musculoskeletal anomalies; OMIM 211910), which is inherited as an autosomal recessive (111); and Guadalajara camptodactyly II (camptodactyly, intrauterine growth retardation, mental retardation, short second toe, and musculoskeletal changes; OMIM 211920), which is inherited as an autosomal recessive disorder (112). In addition, camptodactyly has been reported as a recessive disorder with ichthyosis (113), and as a dominant with scoliosis (114), with symphalangism (115), and with brachydactyly (116).

Camptodactyly is seen as a feature of more than 50 conditions and is frequently associated with chromosomal anomalies.

### 160.3.10 Ectrodactyly

The term ectrodactyly (from the Greek “*ektromo*,” denoting abortion, and “*daktylos*,” finger) theoretically should be reserved for a specific hand anomaly characterized by transverse terminal aphalangia or partial to total absence of the distal segments of fingers. However, the term has been used for the split-hand or lobster-claw anomaly and the EEC syndrome (ectrodactyly, meaning split hand, ectodermal dysplasia, clefting) and so has come to be misleadingly associated with split hand.

The “true” ectrodactyly anomaly may involve one or more phalanges (aphalangia), one or more digits (adactylia), or the full hand (acheiria), and even part of the upper arm. More severe manifestations are hemimelia or amelia. All these abnormalities are considered to represent various degrees of severity of the same anomaly and may be due to an intrauterine vascular occlusion. True ectrodactyly is usually sporadic and unilateral. Reports of familial ectrodactyly probably represent brachydactyly B. In a study by Birch-Jensen (117), 19 individuals affected with true ectrodactyly had 51 normal children. However, a higher incidence of associated malformations in patients and their families has been reported (118). Certainly, “true” ectrodactyly can be seen with

a wide variety of additional anomalies. Several families have been reported with more than one individual affected with terminal transverse amputations of digits or the whole limb; however, no typical pattern of inheritance has emerged (36,119).

The autosomal dominantly inherited form of isolated ectrodactyly (split hand, lobster claw, or cleft hand/foot) can be quite variable within a family and can even involve absence of the long bones. Typically, there is a medial cleft of the hand, the hand being divided into two portions. Often, there is syndactyly of the remaining fingers, and there can be medial clefting and absence analogous to the hand. Occasionally, polydactyly or triphalangeal thumbs are seen. The limbs can be asymmetrically involved (120). This form of ectrodactyly/split hand is remarkable for skipping generations, and some pedigrees demonstrate reduced penetrance. Not only are there variable features and reduced penetrance within a family, six loci for split hand/split foot have been mapped: *SHFM1* (autosomal dominant; OMIM 183600) on chromosome 7q21 (121); *SHFM3* (autosomal dominant; OMIM 600095) on chromosome 10q24 (122–124); *SHFM4* (OMIM 605289) on chromosome 3q27, caused by mutations in *TP63* (125); *SHFM5* (OMIM 606708), localized to chromosome 2q31 (126,127); *SHFM6* (OMIM 225300), caused by homozygosity for mutations in *WNT10B* (118a,38a); and *SHFM2* (X-linked), localized to a 5.1-Mb interval on chromosome Xq26 (128,129).

The combination of ectodermal dysplasia (involving teeth, hair, and nails), ectrodactyly (split hand), and cleft lip/palate (EEC) is striking (130,131). In addition to this triad, genitourinary and lacrimal duct anomalies and choanal atresia can be seen. The features can be variable between affected members of the same family. The degree of keratosis and urinary tract involvement is also inconsistent among affected family members (132). There are at least four chromosomal loci for EEC. EEC1 (OMIM 129900) maps to chromosome 7q11.2–q21.3 based on a number of patients with chromosomal aberrations in this region (133). EEC3 and formerly EEC2 (OMIM 604292) result from heterozygosity of mutations in the tumor protein p63 (*TP63*) gene on chromosome 3 (115,134).

Adams–Oliver syndrome (OMIM 100300) is a syndrome of limb absence anomalies (“true” ectrodactyly) and scalp defects. Autosomal dominant inheritance with variable expression has been reported in several families (135). Scalp defects (cutis aplasia congenita) may vary in size and may occasionally overlie skull defects. The distal limb defects are transverse and may involve only the distal portion of the digits or may involve more of the limb, with absence of hands or feet. Polydactyly has been reported (99). Some cases have remarkable cutis marmorata telangiectasia (136) or cutis aplasia on other parts of the body. Brain anomalies (structural and functional), as well as cardiac and renal abnormalities (137), may be seen. The manifestations are so variable that it is easy to

miss an affected relative unless there is careful examination. The features of this syndrome are very suggestive of a vascular disruptive sequence.

## 160.4 PREDOMINANT LIMB INVOLVEMENT WITH OTHER ASSOCIATED ABNORMALITIES

### 160.4.1 Catel Manzke Syndrome

The combination of Pierre–Robin sequence (cleft palate, glossoptosis, and micrognathia) together with bilaterally short second metacarpal and accessory proximal phalanx of the index finger, giving radial clinodactyly of the index finger, has come to be known as the Catel Manzke syndrome (OMIM 302380) (138). Affected individuals may also have knee defects and congenital heart defects. There is an excess of affected males, suggesting that the inheritance may well be X-linked recessive (139).

### 160.4.2 The Poland Anomaly

The two major components of the Poland anomaly (OMIM 173800) are unilateral symbrachydactyly and ipsilateral aplasia of the sternal head of the pectoralis major muscle. Clinically, there is unilateral absence of the normal anterior axillary fold and shortening or reduction of the limb (140). Most reports of the Poland anomaly indicate that cases are sporadic, though familial cases have been reported (10,141). Etiology is unknown, but early in utero vascular compromise has been proposed (14,142).

The isolated malformations of either symbrachydactyly or unilateral aplasia of the sternal head of the pectoralis major muscle are also sporadic. However, David and Winter (143) recently reported familial absence of the pectoralis major and other chest muscles. Poland anomaly has been found to be more common in males (3:1), and the right side is more commonly involved than the left (2:1) (142). Analogous malformations have been seen in the lower limb. Several reported cases have been associated with the use of vascular constricting agents by the mother in early pregnancy (140). The question of an increased risk for leukemia in the Poland anomaly has been raised (144).

The Poland anomaly has also been seen in association with other skeletal anomalies such as radioulnar synostosis, Sprengel deformity, and coalition of the carpal bones, camptodactyly, polydactyly, skin dimples, deficiencies of the rib cage, scoliosis, and kyphosis. Other skeletal anomalies include cervical ribs, clubfoot, metatarsus adductus, and syndactyly of the toes. Visceral anomalies reported include dextrocardia, herniation of the lungs, inguinal and umbilical hernias, cryptorchidism, ipsilateral hypoplasia of the kidney, coloboma of the optic disc, encephalocele, and microcephaly (142). Features of Poland syndrome also have been seen in individuals with Möbius, Goldenhar, and Adams–Oliver syndromes (145–147).

### 160.4.3 Rubinstein–Taybi Syndrome

Individuals affected with Rubinstein–Taybi syndrome (OMIM 180849) typically have broad toes and thumbs and characteristic facies with a beaked nose (148). The facies is unusual even in infancy, and in addition to the prominent (beaked or pinched) nose, the columella is long and protrudes below the alae nasi. There is an antimongoloid slant to the eyes, with arched eyebrows and a highly arched palate. The ears may be malrotated and usually have thickened helices (149). The broad thumbs and toes are very characteristic and appear spatulate, short, stubby, flattened, and wide. The broad-toed appearance is the result of both soft-tissue and bony changes, which can be seen on radiographs of the terminal phalanx. Duplication of the proximal or distal phalanx of the thumb has been reported (150). All reported patients have been mentally retarded (with IQ estimates less than 50), and microcephaly is seen in more than half the cases. Electroencephalographic abnormalities have been reported, as has absence of the corpus callosum. Short stature is a common feature. In a study of 105 patients, approximately 80% were less than the 3rd percentile for height (148). Other features that have been noted are cardiac malformations, joint laxity, increased deep tendon reflexes, stiff awkward gait, severe keloid formation, cryptorchidism, increased propensity toward malignancy, duplicated kidneys or ureters, absence of the kidney, and hydronephrosis or hydroureter (8). There are many abnormal radiographic findings; however, none are pathognomonic for Rubinstein–Taybi syndrome. They include short and wide terminal phalanges of the thumbs and great toes; short, wide, and tufted terminal phalanges in most fingers; flaring of the ilia; and retardation of skeletal maturation (9).

Breuning et al. (151) identified the candidate region for Rubinstein–Taybi syndrome to chromosome 16 (16p13.3) by studying those patients with the disorder and reciprocal translocations. Petrij et al. (152) then showed that the breakpoints at 16p13.3 that were demonstrated in Rubinstein–Taybi patients were restricted to a region containing the gene for the human CREB-binding protein (*CREBBP*). They showed, furthermore, that point mutations in *CREBBP* could produce Rubinstein–Taybi syndrome. A certain level of *CREBBP* is essential for normal development. It is a nuclear protein that participates as a coactivator in cyclic-AMP-regulated gene expression and thus can affect various signal transduction pathways. In addition to those in *CREBBP*, mutations have also been identified in *EP300* (153). Both *CREBBP* and *EP300* are potent histone acetyltransferases, and part of the pathogenesis of this disorder may be due to abnormal chromatin regulation of an extensive number of genes.

### 160.4.4 Coffin–Siris Syndrome

Sparse scalp hair, generalized hirsutism, intrauterine and postnatal growth retardation, mental retardation, coarse

facial features, full lips, and hypoplastic distal phalanges and nails, particularly of the fifth finger and lateral toes, characterize Coffin–Siris syndrome (OMIM 303600) (154). Affected individuals have recurrent respiratory problems and feeding difficulties (22). Structural brain anomalies, partial gastric outlet obstruction, and cardiac anomalies have also been reported (155). The disorder was mapped to Xp22.2 (156), and deletion, nonsense, and missense mutations have been identified in *RKS2* (157). Interestingly, *RKS2* has been shown to activate *CREBBP* in vitro, suggesting that a similar pathway produces both Coffin–Siris and Rubinstein–Taybi syndrome (158).

### 160.4.5 Fanconi Anemia (Pancytopenia Dysmelia)

Fanconi anemia (OMIM 227650) is an autosomal recessive disorder characterized by pancytopenia, hyperpigmentation, short stature, and radial and renal defects. In some cases, not all these clinical features are present, and the severity of the features present can be extremely variable (159).

The pancytopenia is usually progressive. Average age of onset has been estimated as 8 years, and all marrow elements are involved. However, anemia may precede a decrease in white blood cells or platelets or vice versa. Reports of the onset of hematologic symptoms have varied from 17 months to 22 years. Fetal hemoglobin has been recorded as elevated, and in some cases there have been reduced numbers of erythrocytes and leukocytes and decreased levels of platelet hexokinase (160). Hyperpigmentation of the skin is probably the most consistent clinical feature and appears as fine generalized hypermelanosis, often presenting before hematologic manifestations and increasing with age. Café-au-lait spots are also seen. Pre- and postnatal growth deficiency is frequent, also associated with microcephaly. About 20% of affected individuals are mentally retarded. The most common bony defects are radial ray abnormalities with hypoplastic, absent, digitalized, or supernumerary thumbs; hypoplasia of the first metacarpal; and hypoplasia or absence of the radius and greater multiangular and navicular bones. Bifid thumbs, retarded skeletal maturation, osteoporosis, microcephaly with thick calvaria, syndactyly, and hip dislocations have been reported (161,162). Patients should be evaluated for renal abnormalities, and those with external ear anomalies should also be evaluated for associated deafness. Other reported abnormalities include spina bifida, Klippel–Feil anomalies, scoliosis, rib abnormalities, Sprengel deformity, and flat or clubbed feet.

Complications usually result from pancytopenia with bleeding, pallor, and recurrent infections. Therapy with steroids, bone marrow transplantation, and granulocyte colony-stimulating factor have been helpful for the pancytopenia, although life expectancy is reduced. Affected individuals have a predisposition to leukemia and other

tumors. Cancer deaths may be increased for the heterozygous carriers, though this is not completely clear (163). In patients with Fanconi anemia, chromosomal aberrations are seen and include a number of chromatid breaks, gaps, exchange figures, and endoreduplication, suggesting a defect in DNA repair.

Fanconi anemia is inherited as an autosomal recessive trait, except for one X-linked locus (*FANCB*; OMIM 300514), and genetic heterogeneity has been clearly established, with at least 13 genetic subgroups (164). Six genes responsible for the phenotype have been identified. Almost 80% of cases of Fanconi anemia can be accounted for by defects in either *FANCA* or *FANCC*. The Fanconi anemia (FA) nuclear complex is composed of the FA proteins A, C, E, F, and G, and is essential for protection against chromosome breakage. This complex activates the downstream protein *FANCD2* by monoubiquitination. This action then produces an association with the *BRCA1* (OMIM 113705) protein at sites of DNA damage (165). Thus this complex and process are essential for maintaining genomic stability.

#### 160.4.6 Aase Syndrome (Blackfan-Diamond with Thumb Anomalies)

Triphalangeal thumbs with hypoplastic anemia and growth deficiency have been reported in several sets of sibs (1a). The syndrome (OMIM 105650) also includes hypoplastic (normochromic, normocytic) anemia, present from infancy. Leukocytes and thrombocytes are normal, although fetal hemoglobin may be increased (166). Cardiac anomalies, cleft lip, and mild mental retardation can occur. Steroid therapy may be effective in some cases (167). In some patients, heterozygosity for mutations in *RPS19* on chromosome 19q13.2 have been identified (168). A second locus for the disease has been localized to chromosome 8p23.3 (169).

#### 160.4.7 Thrombocytopenia–Absent Radius Syndrome (Thrombocytopenia Radial Aplasia Syndrome)

Thrombocytopenia–absent radius (TAR; OMIM 274000) syndrome is considered to be an autosomal recessive and dominant trait, although consanguinity has not been truly reported (170). The cardinal clinical features are thrombocytopenia (usually with symptoms in the newborn period) and bilateral absence of the radius with the presence of both thumbs (171).

The thrombocytopenia is congenital and has a hypomegakaryocytic basis. Thrombocytopenia gradually improves over the first 2 years, and platelets may even be in the normal range in adulthood. Viral illnesses, particularly gastrointestinal viral illness, will often aggravate the thrombocytopenia. Leukemoid reactions are seen in 60–70% of patients during the first year. Eosinophilia has been reported in 50% of the patients. Anemia is

thought to be the result of blood loss but may be due to hypoplasia of red blood cells during the first year (171). The radius is absent bilaterally in all cases (Figures 160-7 and 160-8). The ulna is absent bilaterally in about 20% of the cases and is frequently hypoplastic in other cases. The humerus may be short and dysplastic. Thumbs are always present. Anomalies of legs and hips are occasionally seen (e.g. dislocated hips, tibial torsion, abnormal tibiofibular joints, stiff knees, dislocation of the patella, and camptodactyly of the toes with occasional clubfoot) (172). Congenital cardiac abnormalities are seen in one-third of the cases, the most frequent being tetralogy of Fallot and septal defects. Slightly short stature is the rule.

Complications are related to thrombocytopenia and symptomatic bleeding. This could be prevented by proper platelet transfusion. There may be delayed motor function because of hand anomalies; however, eventual good function can be expected. Other complications of the skeletal anomalies include nerve compression of the wrist and arthritis. TAR patients seem to have an increased incidence of allergy to cow's milk, which precipitates episodes of diarrhea and low platelets. The molecular etiology appears to be complex, thus explaining what

**FIGURE 160-7** Thrombocytopenia–absent radius syndrome. Radiographs of chest and upper limbs. Note absence of radius bilaterally, presence of thumb, and shortening of ulna.

**FIGURE 160-8** Infant with TAR syndrome. Note curved short forearm, ulnar deviation of the hand, and presence of the thumb bilaterally.

appeared to be both autosomal recessive and dominant forms of the disease. Klopocki et al. (172a) found that TAR syndrome results from a 200-kb microdeletion on chromosome 1, but the deletion itself is not sufficient to produce disease; another genetic modification is probably necessary to produce TAR syndrome.

Differential diagnosis should include Nager syndrome, pseudothalidomide syndrome, and Fanconi anemia. Ultrasound demonstration of absence of the radius and cordocentesis for platelet counts have resulted in accurate prenatal diagnosis.

### 160.4.8 Orofaciodigital Syndromes

The orofacioidigital (OFD) syndromes have been subdivided into five types, though seven types have been described. They are somewhat similar clinically but have different patterns of inheritance and different associated anomalies (173,174). In all types, the clinical manifestations of the face are striking, with hypertelorism, epicanthal folds, micrognathia, epidermoid cysts, hypotrichosis, and hypertrophic frenula with clefts of the alveolar margin, lips, and tongue. There is dystrophia canthorum, a broad nasal root, and hypoplasia of the alar cartilage and malar bone (6).

OFD type I (Papillon–Leage; OMIM 311200) is clinically distinguished by cleft palate, frenular hypertrophy, thick alveolar bands, aplasia of the nasal alae, ventral clefts and hamartomas of the tongue, dental anomalies, alopecia, and evanescent milia in infancy. Mental retardation is seen in approximately 50% of the cases and is apparently associated with central nervous system malformations, frequently agenesis of the corpus callosum. Polycystic renal anomalies have been seen in the kidneys of several autopsied cases. On radiographs, OFD type I is characterized by brachydactyly (due to short metacarpals, metatarsals, and phalanges and usually showing an irregular distribution), clinodactyly, syndactyly, camptodactyly, and cone-shaped epiphyses. Preaxial polydactyly has been seen in a few cases. OFD type I is an X-linked dominant disorder, which maps to chromosome Xp22.3–p22.2 (175), and hemizygosity for mutations in the gene *CXORF5* have been identified (176).

OFD type II (Mohr; OMIM 252100) is clinically distinguished by normal intelligence, normal hair, normal teeth, midline pseudocleft of the upper lip with associated midline hypertrophic frenula, and no lateral oral frenula. Affected individuals have bilateral hallucal polysyndactyly and conductive hearing loss. There is polysyndactyly of the toes, usually symmetrical with partial reduplication of the hallux, and postaxial polydactyly, primarily of the hand. Clinodactyly, brachydactyly, metaphyseal irregularity and flaring, and supernumerary sutures of the skull are also seen (9).

OFD type III (OMIM 258850) is very similar to type I but in addition has alternately see-saw winking of the eyelids and abnormal extraocular muscles. This entity

has been described only rarely. OFD type IV (OMIM 258860) is very similar to type II but in addition has short ribs, postaxial polydactyly, talipes, and severe tibial dysplasia. Both pre- and postaxial polydactyly are present. This syndrome overlaps the Majewski type of short rib-polydactyly syndrome (type II). OFD type VI (OMIM 277170), or Varadi–Papp syndrome, is distinguished from the other OFD types by the metacarpal abnormalities with central polydactyly and cerebellar abnormalities (177). There is some phenotypic abnormality with Joubert syndrome.

### 160.4.9 Holt–Oram Syndrome

Holt–Oram syndrome (HOS; OMIM 142900) is characterized by autosomal dominant inheritance (with penetrance of at least 90%), congenital heart disease, and radial ray defects. The characteristic hand malformation is digitalization of a triphalangeal thumb so that the thumb is attached in the same plane as other fingers. However, in some cases, the thumb is absent or rudimentary. In addition, the more severe cases show absence or hypoplasia of the radius or even the ulna and humerus. Wrist radiographs are particularly important. Abnormal scaphoid bone and an abnormal first metacarpal-to-first distal phalanges ratio may identify otherwise apparently normal gene carriers (178). Cardiovascular abnormalities are variable. The most common cardiac defect is an atrial septal defect of the ostium secundum type. Other described defects are patent ductus arteriosus, pulmonary hypertension, ventricular septal defect, and transposition of the great vessels with a prolonged P–R interval. Marked variability of limb and heart malformations may occur within the same family. The bony changes that may be seen radiographically are triphalangeal, hypoplastic, proximally placed, or absent thumb; an abnormally shaped scaphoid bone; additional carpal bones or lack of ossification of the carpals, particularly the os centrale; a long ulnar styloid; carpal fusions; an apparent increase in length of the first metacarpal and shortening of the fifth middle phalanx with clinodactyly; a prominent or posterior projection of the medial epicondyle; clavicular hypoplasia; deformed humeral head; and small rotated scapulae (179).

Terrett et al. (180) studied seven families with HOS and established linkage to chromosome 12q in five families. In 1997, both Li et al. (181) and Basson et al. (182) demonstrated that HOS is due to heterozygosity in the *TBX5* gene. *TBX5* is one of the T-box genes involved in DNA binding. It is known to bind to NKX2-5 and synergistically promote cardiomyocyte differentiation. In HOS, there are some genotype–phenotype correlations (183). Defects producing null alleles are predicted to produce both limb and heart defects; however, specific missense mutations produce either significant cardiac defects with minor skeletal anomalies, or the converse.

Clinically, HOS is distinct from other radial ray defect syndromes in that there are no abnormalities of the kidneys or gastrointestinal tract, no deafness, no ear malformations, no mental retardation, and no specific hematologic disorder.

#### 160.4.10 Focal Femoral Hypoplasia (Proximal Femoral Focal Deficiency)

In focal femoral hypoplasia, variable deficiency of the proximal segment of the femur either unilaterally or bilaterally occurs with preservation of the distal part of the limb. There is a continuum of involvement starting most proximally, involving just the femoral head, and extending to involving the lower limb with complete absence of the femur. Severely involved cases may even fall into the femur–fibula–ulna (FFU) complex. Some cases have unusual facies (see later). Typically, most cases of proximal femoral focal deficiency (PFFD) are sporadic with no known etiology.

When the pattern of long bone loss in the lower limb is analyzed, two specific patterns emerge: FFU complex and femur–tibia–radius (FTR) complex. Among PFFD patients, 50% also have a fibular deficiency and 25% have an ulnar deficiency (FFU). Among these FFU patients, usually all four limbs are involved, but there may be marked asymmetry. Variations include coxa vara to complete femur absence, shortened ulna to humero-radial synostosis, and small fibula to complete absence. Usually no spine or visceral anomalies are present. The hand and foot are relatively spared, but anomalies have been reported (4).

In the FTR pattern, the deficiency at the distal end of the femur is most important. Loss of the tibia may be most striking, but any combination of loss may occur. The complex tends to be seen more in genetic forms of lower limb deficiency as compared with PFFD and FFU, which appear to be sporadic (184). The FTR pattern was also seen in thalidomide embryopathy (4).

#### 160.4.11 Femoral Hypoplasia–Unusual Facies Syndrome

A distinct pattern of malformation characterized by Daentl et al. (185) was designated femoral hypoplasia–unusual facies syndrome (OMIM 134780) (Figure 160-9). Clinical features include femoral hypoplasia, usually on the severe end of the spectrum, and the unusual facial features of up-slanting palpebral fissures, short nose with broad nasal tip, long philtrum, thin upper lip, micrognathia, and cleft palate. In addition, renal anomalies, lower vertebral anomalies, and deformed pelvis have been reported. With multiple surgeries and the use of prosthetic devices, most patients are ambulatory and functional. Intelligence is completely normal. Occasionally, with severe micrognathia, feeding and respiratory problems occur.

Shortening of the humerus, restricted motion at the elbows, and Sprengel deformities found in some infants would suggest that this syndrome is not confined to the lower limbs and that a similar mechanism could be acting on both upper and lower limbs. All reports so far have been of sporadic cases; however, an association with maternal diabetes has been suggested.

#### 160.4.12 Hand–Foot–Uterus Syndrome (Hand–Foot–Genital Syndrome)

The hand–foot–uterus syndrome (OMIM 140000) is an autosomal dominantly inherited condition with variable expressivity (186). Clinical features include small feet with unusually short halluces and short, abnormal thumbs. Females with the disorder have duplication anomalies of the genital tract and decreased fertility. Genital tract anomalies are variable but are thought to represent different degrees of expression of the same underlying developmental problem. Duplication of the uterus varies in severity from a full double uterus to a uterus duplex unicornis. In addition, some patients have duplication of the cervix with a septate vagina. These structural anomalies result in fertility complications; however, normal pregnancies are possible. Males have been reported with cryptorchidism and hypospadias; however, these seem to be distinct embryologically from the female genital duplication anomalies (187). Congenital heart disease has been reported in some patients; therefore, a careful cardiovascular examination is warranted.

Radiographic findings include short first metacarpals and metatarsals, short fifth fingers with clinodactyly, trapezium–scaphoid fusion in the wrist, cuneiform–navicular fusion in the foot, an os centrale, and a long ulnar styloid (186).

The gene defective in hand–foot–genital syndrome is *HOXA13* (188). Identified mutations in *HOXA13* have included stop codons, expansion of polyalanine tracts, and missense mutations in a highly conserved domain of the protein (189).

#### 160.4.13 Focal Dermal Hypoplasia (Goltz Syndrome)

Focal dermal hypoplasia (FDH; OMIM 305600) has been observed almost exclusively in females; however, there are reported cases of affected males (190,191). It appears to be an X-linked dominant condition with increased lethality in males. Clinical features include cutaneous changes, skeletal defects, digital malformations, ocular anomalies, and oral/dental anomalies (192).

The most striking clinical features in all the cases of this syndrome are the widespread foci of dermal hypoplasia with herniation of fat (appearing as yellow-brown nodules), red streaking of the skin, and papillomas of the lips, gums, vulva, and anus. The areas of dermal hypoplasia appear as atrophy or absence of skin, but the epidermis is

**FIGURE 160-9** Focal femoral hypoplasia with unusual facies syndrome. Note the short upper leg, short nose with broad nasal tip, long philtrum, thin upper lip, micrognathia, and left equinovarus deformity of the foot.

intact. Telangiectasia and hypo- and hyperpigmentation are seen. Surgery is indicated for removal of lesions (e.g. angiofibromas) that are in areas prone to trauma. The hair is sparse, sometimes blonde or almost white in color, with patchy areas of alopecia. Nails may be absent, hypoplastic, dystrophic, spoon-shaped, or grooved. Teeth are congenitally absent or malformed (193).

Digital anomalies include syndactyly, polydactyly, camptodactyly, and absence deformities. Most individuals have short stature and can have vertebral anomalies leading to kyphosis and scoliosis. There is asymmetry of the face, trunk, and limbs. Several different ocular changes have been described: microphthalmia, colobomas, strabismus, and nystagmus. There is occasional mental retardation.

The degree of clinical severity varies widely. Some patients may have only skin changes or simply syndactyly, whereas others may show full manifestations of the syndrome with microphthalmos, bilateral coloboma of the iris, ectopia lentis, hypoplasia of the teeth, and severe cutaneous, skeletal, and digital malformations. Happle and Lenz suggested the patchiness represents mosaicism with death of the cells that have the affected X activated (194). Mutations producing Goltz syndrome have been identified in the porcupine, drosophila, homolog of, (POCN) gene (195).

#### 160.4.14 Ulnar–Mammary Syndrome

The combination of ulnar ray defects, hypoplasia or aplasia of mammary glands, hypoplasia of nipples, hypoplasia of apocrine glands with reduction in body odor, and genital anomalies in males is an autosomal dominant disorder (OMIM 181450) (196). The ulnar ray defect may be so mild as to involve only stiffness of the distal interphalangeal fifth finger joint or hypoplasia of the fifth fingernail, or may present with complete absence of one to three ulnar rays of fingers (197). Other reported visceral anomalies include dental abnormalities, subglottic stenosis, pyloric stenosis, anal stenosis, imperforate hymen, kidney malformations, hypodontia, and pectoralis muscle hypoplasia.

Carpals and tarsals may also be involved, postaxial polydactyly has been seen, and feet may show hypoplasia of toes. Axillary and body hair is sparse, but pubic hair is normal. Nipple hypoplasia may lead to the inability to breast-feed. Affected males may have cryptorchidism, small penis, and small testes with decreased sperm counts and infertility. In a large family, the chromosomal location for ulnar-mammary syndrome was identified on chromosome 12q24.1 (198). Further analysis demonstrated that the defective gene is *TBX3* (199), a T-box gene.

## Arthrogryposes (Multiple Congenital Contractures)

Judith G Hall

UBC and Children's and Women's Health Centre of BC, Department of Medical Genetics,  
BC's Children's Hospital, Vancouver, BC, Canada

### 161.1 INTRODUCTION

Arthrogryposis multiplex congenita (AMC) is a term that has been used for almost a century to describe conditions with nonprogressive multiple congenital joint contractures. The conditions that have been called arthrogryposis range from well-known syndromes to nonspecific combinations of joint contractures. The term has become descriptive rather than diagnostic and is now used in connection with a very heterogeneous group of patients and disorders, all of which have in common multiple congenital joint contractures. We have begun to realize that over 350 specific disorders are or maybe associated with multiple contractures in the newborn, and that, although most improve over time, some are progressive.

Arthrogryposis has been said to be a rare condition, but in fact it has an incidence somewhere between 1 in 3000 and 1 in 5000 live births, much more common than most genetic disorders and congenital anomalies (1–4). Many kinds of congenital contractures, such as clubfeet and dislocated hips, are relatively quite common. One in 100 to 200 infants is born with some type of congenital contracture. The term arthrogryposis implies a more generalized involvement, with multiple joints having congenital contractures, and is most often reserved for conditions that involve more than one part of the body.

The medical literature on arthrogryposis (multiple congenital joint contractures) is very confusing. Over the past 50 years, more than 3000 articles have been published describing various types of arthrogryposis, but the term has been used very loosely, initially as a diagnostic term but more recently as a clinical sign or as a general category of disorders. In addition to the imprecise use of the term, the medical literature on arthrogryposis is confusing, because many authors fail to fully describe the clinical features of their cases, or to separate subgroups. In the past, authors have often lumped together several

patients with congenital contractures, who in actuality represent different specific entities, and have then made generalizations about recurrence, management, prognosis, and treatment. More recently, responsible genes have been identified for many specific types of arthrogryposis and the range of variability is being defined (see [Tables 161-7 and 161-8](#)). This chapter attempts to sort out some of the major known clinical entities with congenital contractures, to describe a clinical approach to distinguishing heterogeneity, to discuss the investigation of the individual with congenital contractures, and to make some comments about genetics, recurrence risk, prenatal diagnosis, and therapy (2,5–8).

It has become increasingly apparent, both from animal studies (9–12) and from human work (13–22), that anything that leads to decreased movement *in utero* may also lead to congenital contractures or fixation of joints that will then be present at birth. Even prolonged hypotonia may lead to congenital contractures.

The early studies of Drachman and Coulombre (11) demonstrated that temporary paralysis by curarization of chick embryos at various times in development resulted in multiple congenital contractures. The immobilized chick developed fixation of different joints, depending on the time in morphogenesis that immobilization occurred. DeMyer and Baird (10) have shown that removal of amniotic fluid during gestation in rats could lead to limitation of movement of joints and intrauterine growth retardation, with the development of generalized contractures by birth. Most recently, early amniocentesis has also been associated not only with congenital contractures of the foot, but with arthrogryposis (23).

Moessinger (12) noted that rat fetuses that had been paralyzed *in utero* by curare developed a set of anomalies he designated the “fetal akinesia deformation sequence.” He noted that these findings were similar to anomalies seen in the human Pena–Shokeir syndrome (type I),

including multiple joint contractures, pulmonary hypoplasia, micrognathia, intrauterine growth retardation, short umbilical cord, and polyhydramnios. These clinical features are seen in several specific conditions (16,24,25). When any one of them is present, the others should be looked for.

It appears that any process that limits movement during development of the fetus or embryo may lead to congenital contractures. The *in utero* process may well be similar to the postnatal process of wearing a cast for a broken bone. When the cast is taken off, there is usually residual limitation of movement in joints that were immobilized. Swinyard (18) has called this a “collagenic response,” with thickening of the joint capsule and fibrous development in muscle tissue. Undoubtedly, lack of movement either produces a set of cytokines or fails to produce a set of cytokines that ultimately leads to this connective tissue response. The growing embryo or fetus that has superimposed limitation of movement may develop even more marked contractures because the process of growth may compound the contractures leading to additional deformation. In this regard, most congenital contractures may be considered deformations rather than primary malformations (1003), since the limbs are usually formed normally and then develop secondary changes. The timing during development probably plays a critical role in the severity of contractures, in the position of joints, and in the secondary changes that may occur in other organ systems (16,25,84). It would appear that lack of movement or hypotonia takes over a month to produce contractures in the third trimester, but the length of time may be less in the first and second trimesters.

The potential causes of limitation of movement *in utero* include:

1. Myopathic processes, including myopathies and abnormal muscle structure or function, such as absence or loss of muscle tissue and congenital myopathies
2. Neuropathic processes, including abnormalities in nerve structure or function, either central or peripheral; failure of nerves to form, migrate, or myelinate; and congenital neuropathies
3. Neuromuscular end-plate abnormalities, including abnormal structure receptors and transmitters
4. Abnormal connective tissue, including bone, joint, and tendon abnormalities; skin abnormalities (such as restrictive dermopathy); and abnormal tendon attachments
5. Limitation of space or restriction of movement within the uterus, as in the case of twins, structural anomalies of the uterus, amniotic bands, fibroids, or decreased amniotic fluid, as with leakage
6. Problems related to maternal illness, including maternal infections, interference with fetal neurotransmitters as by antibodies, etc.
7. Maternal exposures related to medications, drugs, and environmental factors, such as muscle relaxants, high temperature, fever, etc.
8. Compromise of the blood supply to the placenta and/or the embryo/fetus.

## 161.2 APPROACH

An approach to sorting out various types of congenital contractures (Table 161-1) includes taking a careful history of the pregnancy and delivery; a full family history; a detailed physical examination with documentation of what parts of the body are involved in the process; photographs at different ages and measurements including range of movement of various joints; a natural history of complications and response to therapy; laboratory data, such as muscle biopsies; imaging studies; autopsy results, including central nervous system (CNS) histopathology; chromosome studies; and molecular studies as appropriate, including comparative genomic hybridization (CGH) microarray. This kind of evaluation has proven to be important and necessary in distinguishing different types of arthrogryposis. Thus, in the course of the investigation of a patient with congenital contractures, definition of all these areas will be helpful in arriving at a specific diagnosis.

### 161.2.1 Histories

Pregnancy history, delivery history, family history, and natural history over time are all extremely important, and several particular points should be kept in mind in their analysis.

**161.2.1.1 Pregnancy History.** The pregnancies of infants with multiple congenital contractures do have an increased frequency of complications (27). The question of intrauterine infections should always be considered in the evaluation of infants with congenital contractures, particularly those with neurologic impairment. Not infrequently, the mother has had an infection that could have led to secondary fetal CNS damage, and she may not even be aware of it. It is appropriate to do immunoglobulin M studies in the newborn with congenital contractures, looking for increased levels that would indicate intrauterine infection, and in addition, specific titers can be measured (coxsackievirus, enterovirus, Akabane virus, etc.). Seasonal and geographic variables may be indicators of the particular viral infection that should be investigated. Maternal fever greater than 39°C for an extended period may lead to CNS damage. Secondary contractures may occur in the fetus because of abnormal nerve growth or migration association with maternal hyperthermia (28). Chronic maternal illness such as diabetes mellitus, multiple sclerosis, myotonic dystrophy, or myasthenia gravis are important because they have been associated with arthrogryposis in the newborn due to secondary effects, such as abnormal glucose metabolism, increased triple

**TABLE 161-1 Clinical Evaluation****History**

Pregnancy (anything decreasing *in utero* movement leads to congenital contractures)

- Illness in mother, chronic or acute (diabetes, myasthenia gravis, myotonic dystrophy, etc.)
- Infections (rubella, rubeola, coxsackie, enterovirus, Akabane, etc.)
- Fever ( $>39^{\circ}\text{C}$ , determine timing in gestation)
- Nausea (viral encephalitis, position of baby, etc.)
- Drugs (curare, robaxin, alcohol, dilantin, addictive drugs, misoprostol, etc.)
- Fetal movement (polyhydramnios, fetal kicking in one place, "rolling," decreased)
- Oligohydramnios, chronic leakage of amniotic fluid
- Polyhydramnios, hydrops
- Trauma during pregnancy (blow to the abdomen, attempted termination, car accident, etc.)
- Other complications during pregnancy such as bleeding, abnormal lie, threatened abortion, etc.
- Prenatal diagnosis (early amniocentesis, ultrasound studies, etc.)

**Delivery history**

- Presentation (breech, transverse, etc.)
- Length of gestation
- Traumatic delivery (limb position, CNS, fracture, etc.)
- Intrauterine mass (twin, fibroid, etc.)
- Abnormal uterine structure or shape
- Abnormal placenta, membranes, or cord length or position
- Time of year, geographic location

**Family History**

- Marked variability within family
- Change with time – degenerate vs improve
- Increased incidence of congenital contractures in second- and third-degree relatives
- Hyperextensibility or hypotonia present in family member
- R/O myotonic dystrophy, myasthenia gravis in parents (particularly mother)
- Consanguinity
- Advanced parental (mother or father) age
- Increased stillbirths or miscarriages
- If more than one consecutively affected child, consider maternal antibodies to fetal neurotransmitter

**Newborn Evaluation****Description of contractures**

- Which limbs and joints
- Proximal vs distal
- Flexion vs extension
- Amount of limitation (fixed vs passive vs active movement)
- Characteristic position at rest
- Severity (firm vs some give)
- Complete fusion or ankylosis vs soft tissue contracture

Other anomalies (contractures are most obvious, look carefully for other anomalies)

**Deformities**

Genitalia (cryptorchid, lack of labia, microphallus, etc.)

Limbs (pterygium, shortening, webs, cord wrapping, absent patella, dislocated radial heads, dimples, etc.)

Jaw (micrognathia, trismus, etc.)

Facies (asymmetry, flat bridge of nose, hemangioma, movement, etc.)

Scoliosis and kyphosis (fixed or flexible)

Dimples (over specific joints or bones)

Skin (hemangioma, defects, hirsutism)

Dermatoglyphics (absent, distorted, crease abnormalities, etc.)

Hernias, inguinal and umbilical, abdominal wall defect

Other features of fetal akinesia sequence

- Intrauterine growth restriction
- Pulmonary hypoplasia
- Craniofacial anomalies (hypertelorism, cleft palate, depressed tip of nose, high bridge of nose)
- Functional short gut with feeding problem
- Short umbilical cord

**Malformations**

Eyes (small, corneal opacities, malformed, ptosis, strabismus, etc.)

CNS (structural malformation, seizures, MR, etc.)

Palate (high, cleft, submucous, etc.)

Limb (deletion anomalies, radioulnar synostosis, etc.)

GU (structural anomalies of kidneys, ureters, and bladder)

Skull (craniosynostosis, asymmetry, microcephaly, etc.)

Heart (congenital structural anomalies vs cardiomyopathy)

Lungs (hypoplasia vs weak muscles or hypoplastic diaphragm)

Tracheal and laryngeal clefts and stenosis

Changes in vasculature (hemangiomas, cutis marmorata, blue cold distal limbs, etc.)

Other visceral anomalies

**Other Features**

Neurologic examination (detailed)

- Vigorous vs lethargic
- Deep tendon reflexes (present vs absent, slow vs fast)
- Sensory intact or not

**Muscle**

- Mass (normal vs decreased)
- Texture (soft vs firm)
- Fibrous bands
- Normal tendon attachments or not
- Changes with time

**Connective tissue**

- Skin (soft, doughy, thick, extensible)
- Subcutaneous (decreased fat, increased fat)
- Hernias (inguinal, umbilical, diaphragmatic, or eccentric)
- Joints (thickness, symphalangism, etc.)
- Tendon attachment and length

**Course****Changes with Time**

Developmental landmarks (motor vs social and language)

Growth of affected limbs

Progression of contractures

Lethal vs CNS damage vs stable vs improvement

Asymmetry (decreases or progresses)

Trunk vs limb changes

Intellectual abilities

Socialization

Feeding problems

**Response to Therapy**

Spontaneous improvement

Response to physical therapy

Response to casting

Which surgery at which time

Development of motor strength proportionate to limb size

Abnormal reaction to drugs

*Continued*

TABLE 161-1 Clinical Evaluation—Cont'd

**Laboratory Evaluation***Tests*

Documentation of range of motion and position with photographs

Radiographs if:

- Bony anomalies (gracile, fusions, extra or missing carpals and tarsals, etc.)
- Disproportionate
- Scoliosis
- Ankylosis
- Dislocation (hips, radial head, patella, etc.)

CT scan, MRI, or functional MRI to evaluate CNS or muscle mass obscured by contractures

Ultrasonic evaluation of CNS, other anomalies, or to establish potential muscle tissue

Chromosome studies or CGH if:

- Multiple system involvement
- CNS abnormality (eye, microcephaly, MR, lethargic, degenerative)
- Streaky or segmental involvement
- Consider fibroblasts if lymphocytes were normal and patient has MR with no diagnosis
- Gene testing if fits known disorder in which gene testing available

Video of movement including facial, range of movement, strength – repeat at regular intervals

Viral culture ± specific antibodies or IgM levels in newborn

Muscle biopsy in normal and affected areas at time of surgery to distinguish myopathic from neuropathic (do special histopathology and electron micrographic studies) – if CPK or unusual muscle response, do muscle biopsy earlier, examine mitochondria

EEG - if seizures or episodes

EMG in normal and affected area

Nerve conduction in normal and affected area

CPK if:

- Generalized weakness
- Doughy or decreased muscle mass
- Progressively worse

Eye examination (opacities, retinal degeneration, etc.)

Maternal antibodies to neurotransmitters, if myasthenia gravis or recurrent affected pregnancies without diagnosis

Spinal muscular atrophy (SMN) DNA testing if accompanying hypotonia

Mitochondrial DNA if other suggestions of mitochondrialopathy

Metabolic screening – see Table 161-16

*Autopsy*

Visceral anomalies

CNS – brain neuropathology

Spinal cord (number and size of anterior horn cells, presence or absence of tracts at various levels)

Ganglion, peripheral nerve

Eye (neuropathology)

Muscle tissue from different muscle groups (EM and special stains, R/O ragged red fibers)

Diaphragm for thickness or hernia

Fibrous bands replacing muscle

Cartilaginous or bony fusion

Tendon attachments

Other malformations, deformations, or disruptions

CGH array if multiple congenital anomalies

Save DNA for molecular testing

CGH = comparative genomic hybridization; CNS = central nervous system; CPK = creatine phosphokinase; CT = computed tomography; EM = electron microscopy; EMG = electromyography; GU = genitourinary; IgM = immunoglobulin M; MR = mental retardation; MRI = magnetic resonance imaging; R/O = rule out.

repeat expansion, or inhibiting fetal neurotransmitters (21) (Table 161-6). A history of nausea in the mother is of importance as a high frequency of pregnancies that result in congenital contractures have been noted to be associated with excessive nausea at various times in pregnancy (27). It is not known whether the nausea is due to a maternal viral infection, to abdominal discomfort, to irritation because of an abnormal positioning of the fetus, or to something else. Use of drugs by the mother during the pregnancy that might lead to decreased movement of the fetus, such as muscle relaxants, drugs that may lead to potential CNS damage and secondarily affect fetal movement (e.g., alcohol), prostaglandins (e.g., misoprostol), and vasoconstrictors, should all be queried about specifically when taking a pregnancy history (18,29). Trauma or surgery during the pregnancy may be associated with the development of multiple contractures. An increased occurrence of congenital contractures associated with failed attempted termination of pregnancy has been observed (30a,30b). Early amniocentesis appears to be associated with a small increased risk for multiple congenital contractures (23). A careful pregnancy history frequently indicates abnormal fetal movement (decreased movement, movement in only one area, or a “swimming

motion”). Polyhydramnios during the pregnancy may indicate fetal compromise (e.g., that the fetus is not swallowing normally). Together with hydrops of the fetus, polyhydramnios is a poor prognostic sign for viability. Long standing oligohydramnios or chronic leakage of fluid may lead to fetal constraint and secondary deformational contractures. An abnormal fetal position may be a clue to intrauterine joint contractures. Both transverse lie and breech positioning are seen with increased frequency in pregnancies that result in arthrogryposis. Prenatal diagnosis is possible for most types of arthrogryposis using real-time ultrasonic evaluation of the fetus looking for movement and range of movement of joints; however, routine prenatal diagnosis usually does not pick up congenital contractures. Because management of the pregnancy may be altered if arthrogryposis is recognized prenatally, it should be considered in situations of an abnormal fetal position, polyhydramnios, or when the mother reports decreased movement (85).

**161.2.1.2 Delivery History.** Delivery history is usually abnormal in arthrogryposis, either because of an abnormal presentation or difficulty in delivery due to the fixed joints. Breech position and even spinal hyperextension are often seen. It is not unusual for a fracture to

occur during delivery (5–10% of the time (31)) or after birth iatrogenically when working with or evaluating the contractures. The presence of fractures in the newborn with arthrogryposis does not specifically imply a skeletal dysplasia since affected individuals often have thin, gracile, osteoporotic long bones (32). Babies with congenital contractures have been erroneously diagnosed as having osteogenesis imperfecta by inexperienced individuals simply on the basis of fractures. However, a form of arthrogryposis and osteogenesis imperfecta (Bruck syndrome) does exist. The length of gestation is usually normal, although certain conditions with congenital contractures, such as trisomy 18, may go past the delivery date, and other factors, such as congenital infections and rupture of membranes, may lead to early delivery. The length of labor is often prolonged because of difficulty in actually delivering due to the unusual position of the fetal joints. Breech and transverse positioning are relatively common, leading to cesarean section. Cesarean section is also often performed due to fetal distress. Both CNS and limb trauma may occur during delivery. Infants in a hyperextended position *in utero* should be delivered by cesarean section to avoid damaging the spinal cord (31).

Careful examination of the uterus for structural uterine anomalies or a uterine mass such as a fibroid is important if cesarean section is performed. The placenta, membranes, and cord insertion need to be examined looking for amniotic bands or signs of vascular compromise. The umbilical cord may be shortened related to decreased *in utero* movement, or may actually be long when wrapped around a limb. In such a case, vascular or mechanical compression of that limb may occur. Ectopic pregnancies are usually associated with congenital contractures.

**161.2.1.3 Family History.** A careful family history is important. There may be marked variability within families as to severity of contractures; congenital contractures in the parents of an affected child may actually have worked themselves out by the time the parents reached adulthood. The lack of normal flexion creases in the adult is a clue that there was lack of normal *in utero* movement. Frequently, family members have other kinds of connective tissue abnormalities such as hyperextensibility, dislocated joints, clubfeet, and dislocated hips (2). A surprisingly large number of children (15–20%) with arthrogryposis have multiple congenital contractures secondary to specific complications, such as hypotonia *in utero*, CNS structural anomalies, or lax connective tissue occurring with a known genetic disorder. For instance, congenital contractures are occasionally seen in association with tuberous sclerosis and neurofibromatosis. Infants with multiple congenital contractures are born more often than by chance to mothers affected with myotonic dystrophy, myasthenia gravis, multiple sclerosis, and arthritis. Thus careful family histories with special attention to relevant disorders should be taken. Consanguinity, multiple stillbirths or miscarriages, and advanced parental (both mother and father) age should be asked about.

## 161.2.2 Physical Examination

Careful newborn examination and documentation is important. Photographs at birth and regularly thereafter are extremely helpful in identifying a specific type of arthrogryposis. Position of contractures as well as active and passive range of motion should be carefully measured and described. It is important to document whether the contractures are proximal or distal, and in flexion or in extension, the amount of limitation, and the characteristic position at rest. Some conditions usually only involved the arms and other usually only the legs (Table 15). Spine and jaw contractures should be looked for. Flexion creases, particularly of the hand, should be documented. The presence of dimples overlying joints with contractures is frequent. Skin webs across joints with limitation of movement are common and may be present at birth or develop with time. The findings may reflect something about the time of onset of the limitation of movement of the affected joint. Assessment of muscle function and strength should be documented at regular intervals. It is important to describe tendon attachments, because “misplaced” tendons and abnormal or missing sesamoid bones in the tendons are frequently seen (33,950). For instance, the patella is often missing or underdeveloped. Limitation of opening of the jaw (trismus) should be defined specifically, because it has significance for feeding and intubation as well as diagnosis (34). Care should be taken when examining the range of motion since iatrogenic fractures may occur during examination in the newborn period.

A variety of additional anomalies, including disruptions, deformations, and malformations, have been seen in children with congenital contractures. These anomalies may well give some clue to the underlying basic process and to the differential diagnosis. Careful documentation of the neurologic status, including the presence of hypotonia or hypertonia as well as the amount and texture of the muscle tissue present, is important. Range of eye movements is important. Eye examination by an ophthalmologist should be done at least once. Other connective tissue findings, such as loose or tight skin, hyperextensibility, and the like, should be documented. Pigmentary changes in the skin, abnormal hair pattern, and the presence of edema or hirsutism should be recorded.

## 161.2.3 Course

The natural history and response to therapy are different in different forms of arthrogryposis. These differences are helpful in distinguishing specific entities but may also indicate the need for different types of therapy. For instance, physical therapy to stretch contractures is usually indicated, but in diastrophic dysplasia this may actually lead to ankylosis of joints. Many forms of arthrogryposis respond well to simple physical therapy and use (e.g., the hands in distal arthrogryposis), whereas others usually require surgical procedures in addition to

physical therapy (e.g., most cases of amyoplasia). Prognosis for children with normal intelligence may be very good and enable independent living and productive lives despite severe handicaps. A rare form of arthrogryposis is prone to malignant hyperthermia, so anesthesia should be undertaken with care in all children with congenital contractures (35). Trismus leads to difficulty with feeding and intubation. Seizures may develop with age (36). Some rare forms include deterioration of mental status. All children with arthrogryposis will have motor developmental delay.

Parents should be encouraged to keep photographic or video records over time. They should keep a notebook of photographs, procedures, consultations, diagnostic tests, growth, response to therapy, and so forth, to illustrate changes and accomplishments over time.

### 161.2.4 Therapy

Treatment of arthrogryptic joints is a controversial topic, probably because there is no one completely successful approach (8,20,37–43,44b,45–52,53b,54,1004,1017). It has become clear that vigorous physical therapy early is very important to avoid muscle atrophy. Splinting, combined with physical therapy, may be preferable to continuous casting. Night splints after surgical procedures are used to maintain the increased range of movement and position. Recently, Botox has been used in mild cases. If surgery is undertaken, muscle biopsy should be performed at least once from an affected area and from a normal area of muscle for comparison. Malignant hyperthermia occurs rarely in association with anesthesia (particularly in myopathies), so care should be taken to monitor temperature during surgery (35,56). Children with arthrogryposis frequently develop otitis (secondary to spending excessive time lying on their backs) leading to decreased hearing and middle ear fluid retention, but rarely have deafness on the basis of sensorineural abnormalities or bony anomalies of the middle ear (57a). Some affected children have feeding problems early, related to uncoordinated swallowing and weak muscles. They often improve over time, but may require G or J tubes initially. Some children need speech therapy. The lungs may be hypoplastic and respiratory support may be needed in the newborn period. Stem cell therapy (involving both muscle and nerve) is not possible at this time, but considering the advances in tissue specific growth factors, may be possible in some combination in the future. Most recently, therapeutic doses of acetylcholine-like drugs may be useful in multiple pterygium syndromes related to receptor subunit deficiencies.

### 161.2.5 Laboratory Tests

On the whole, laboratory tests have not been extremely useful in making a diagnosis in cases of congenital contractures. Electromyography (EMG), muscle biopsies,

nerve conduction studies, and muscle enzyme studies are quite often interpreted as showing nonspecific or disuse changes; however, if they indicate a myopathy (58,59), that may be very helpful in making a diagnosis. Muscle biopsies often show fatty and connective tissue replacement of muscle fibers, variation in muscle fiber size, or decreased fiber diameter; all nonspecific signs of muscle atrophy. However, ragged red fibers and specific myopathic and inclusion changes should be looked for. Radiographs are useful in ruling out specific bone dysplasias and in documenting disproportion, osteoporosis, and scoliosis. Ultrasound studies may help to document the amount of muscle present (51). Magnetic resonance imaging (MRI) and computerized axial tomography (CAT) scans also help to define the amount of muscle present as well as CNS structural anomalies (60). Maternal antibodies to fetal neurotransmitters is a useful test if recurrence is unexplained (21). Many specific genes have been found for specific disorders (Tables 161-7 and 161-8 list known responsible genes and their chromosome locations). Linkage or DNA studies may be warranted depending on clinical features. The genes for over 120 disorders with multiple congenital contractures have been identified. The genes responsible for an additional over 70 disorders with multiple congenital contractures have been found since the last edition. However, no screening DNA chip is available. Interestingly, many genes related to muscle proteins are being identified, even in disorders that had previously been thought to be neuropathic disorders. Chromosome studies and CGH array should be performed in affected individuals with additional structural anomalies (other than deformations) or when mental disability is present, since many microdeletions and duplication syndromes have multiple congenital contractures (Table 161-5). Several metabolic and storage disorders may have multiple congenital contractures at birth making appropriate screening important (Table 161-16).

### 161.2.6 Autopsy

If a child with multiple congenital contractures dies, it is very important to do a complete autopsy. Information on the changes seen in arthrogryposis on autopsy, as well as in normal tissue, demonstrates a wide range of possibilities by present techniques (58–60,62–65). The pathogenesis that is associated with particular patterns of abnormalities is often hard to interpret. Spinal cord sections at multiple levels and muscle pathology from several sites need to be evaluated (62). The finding of specific changes that allow diagnosis is very important to the family if it can establish the risk for recurrence. Structural CNS abnormalities are frequent, including migration and myelination abnormalities. Increased size of ventricles and decreased brain mass as well as structural anomalies of the brain are not uncommon. “Misplaced” tendons are frequently seen; whether these are primary

or secondary changes is not yet clear (950). Thickening of joint capsules and fibrous fatty replacement of muscle are frequent. Major or specific structural abnormalities of organs or brain help to delineate specific conditions. Examination of the eye may be helpful. DNA should be saved for studies or future use, depending on findings.

### 161.2.7 Genetics

Some generalizations can be made about the genetic aspects of arthrogryposis. In the past, when a child with arthrogryposis or congenital contractures was born to normal parents with an unremarkable family history, the parents were given an empiric “polygenic/multifactorial” 5% recurrence risk that they might have another affected child. However, with careful documentation, a specific diagnosis can be reached in at least half of the patients seen with arthrogryposis (2). For instance, amyoplasia appears to have no recurrence risk at all (31,66). Distal forms of arthrogryposis may have as much as a 50% recurrence risk. Multiple forms of X-linked recessive arthrogryposis exist (67–69). In the category of individuals with CNS involvement, consideration of chromosome anomalies, particularly submicroscopic, and mosaicism must be excluded; this sometimes involves fibroblast chromosome studies (70) and microarray studies on two or more tissues. Among children with arthrogryposis and CNS involvement, the recurrence risk may be as high as 25%, with an average risk of 10–15%. (This implies, of course, that there is a high incidence of autosomal recessive disorders or maternal factors within this category.) Recognition that maternal antibodies against embryonic or fetal proteins related to movement can lead to arthrogryposis suggest new avenues of diagnosis. Every effort to achieve a specific diagnosis should be made; however, for those families in which a specific diagnosis cannot be made, the empiric recurrence risk to unaffected parents of an affected child or to the affected individual with arthrogryposis continues to be in the 3–5% range (2).

Prenatal diagnosis is possible in many conditions with congenital contractures, using real-time serial ultrasound studies to evaluate fetal movement (71–80a,81–84). Real-time ultrasound studies at 16, 20, 24, and 32 weeks are recommended, and require 45–60 min of observation related to various joint movement and structural evaluations (84). Nuchal edema and gracile osteoporotic bones may be seen. Chest and lung size should be evaluated since many forms of Pena–Shokeir phenotype have markedly reduced lung size (25,84). There are many reported cases of failure to make the diagnosis in an infant with multiple joint contractures using real-time ultrasound during the second trimester (85). In our experience, the presence and timing of contractures in the second trimester is dependent on the specific condition. In several genetic forms of arthrogryposis, contractures are easily seen by 14 weeks, whereas in others they do not occur until 20 or 24 weeks, or even later. Depending on the condition,

marked intrafamilial variability can be seen (86). Care must be taken to look at each major joint for full range of motion. However, the timing of onset of *in utero* limitation of movement is probably different for different conditions. Nevertheless, congenital contractures are frequently missed prenatally. More than half of cases of amyoplasia, in which contractures are already present at 14 weeks, are missed in spite of having had prenatal ultrasound. The presence of or absence of flexion creases may give clues as to when the movement or failure of movement in the limb occurred. For instance, flexion creases of the fingers and hand are established by 14 weeks of development. Norms for *in utero* movement have now been established (87). If arthrogryposis is diagnosed prenatally, consideration of therapy to increase fetal movement in the second and third trimester should be considered (increased maternal activity, maternal deep breathing, caffeine, etc.), to possibly increase lung volume and lessen the severity of contractures in the limbs at birth, and must be weighed against expected outcome. Early delivery may be considered if lungs are mature since the longer the lack of movement is present *in utero*, the more severe the contractures will be. In the situation of maternal antibodies against fetal neurotransmitters, suppressive steroid therapy is promising. If a family is at risk for recurrence, prenatal diagnosis by real-time ultrasound should be offered in subsequent pregnancies in order to provide appropriate management of an affected pregnancy (84).

### 161.2.8 Developmental Considerations

In humans, the limb bud first becomes obvious during the fifth to sixth weeks of embryonic development. There is a cranial–caudal progression with the upper limb bud development, ahead of the lower limbs. Movement begins as early as 8 weeks in the upper limbs, and can be seen proximally by 9 weeks and distally by 10 weeks. Movement requires an intact neuromuscular unit (84,87). During this time, there is a shifting vascular supply in the CNS, possibly making anterior horn cells vulnerable to hypoxia. Normal joint development in the limbs apparently requires embryo/fetal movement (88) undoubtedly involving embryonic/fetal muscles. Flexion creases in the fingers and palms develop secondary to movement between 12 and 14 weeks.

Rare cases of ongoing pregnancy after attempted termination of pregnancy (30a,30b) or maternal trauma secondary to motor vehicle accidents that would be expected to lead to maternal hypotension and/or compromised vascular supply to a fetus who is later born with congenital contractures allows the establishment of the timing of events. These cases suggest a timing such that events at 8 weeks are associated with limitation of jaw opening and possibly involvement of all four limbs, those at 9 weeks may have involvement of only the upper limbs or all four limbs, those at 10 weeks usually have involvement of all four limbs, and those at 11 weeks

have involvement of only the lower limbs. Some of these cases also have CNS compromise, but some seem to only involve contractures (both extension and flexion) of limbs with fibrous fatty change in muscle. The pathogenesis is still unclear, but these cases of trauma appear to be relevant to amyoplasia and distal IIE (distal arthrogryposis with trismus) as well as the contractures associated with CVS and early amniocentesis (23).

Lung and gastrointestinal tract fetal *in utero* development clearly requires movement (use). In the normal fetus, breathing motions begin around 12 to 14 weeks and become regular by 20 weeks (89). They involve both diaphragmatic and intercostal muscles. In various forms of arthrogryposis, these respiratory movements are decreased leading to suppressed alveolar development, surfactant maturation, and lung size (25,90). Some forms even have poor development or eventration of the diaphragm. Fetal swallowing begins early in the second trimester. Failure to initiate regular swallowing or the presence of blockage of the intestinal tract (such as in gastroschisis or bowel atresia) may lead to polyhydramnios and to delay in maturation of coordinated peristalsis, growth of the length of the bowel, and maturation of gastrointestinal secretions. This kind of delayed development of the gastrointestinal tract is likely to lead to feeding problems in the newborn in infants with arthrogryposis, and they often require tube feeding. However, interestingly, many affected infants “outgrow” the problem.

There seems to be a 3- to 4-month period after birth during which normalization can occur: “catch-up” growth in the lungs may occur so that near-normal respiratory function may be gained; the intestinal motility and secretions may mature and regular feeding may be established; and increased range of motion of joints may be accomplished by physical therapy, casting, and splinting. However, by about 4 months, usually no further gains occur and surgery may be considered.

As genes involved in various types of inherited arthrogryposis are being identified to be components of different types of muscle, consideration of which types of muscle (striated, smooth, cardiac, facial, diaphragm, etc.) are affected in specific forms of arthrogryposis should be undertaken. Furthermore, the issue of primary myopathy versus secondary myopathy (disuse atrophy) must be considered.

### 161.2.9 Prevention and Therapy

Only a few disorders with multiple congenital contractures are preventable or directly treatable at this time. Several maternal (Table 161-6) metabolic disorders (Table 161-16) predispose to CNS damage that can be associated with multiple congenital contractures. If mother is under good metabolic control before becoming pregnant and during pregnancy, this should lead to prevention. Several drugs have been associated with multiple congenital contractures if taken by the mother

during pregnancy. These include muscle relaxants, misoprostol, cocaine, and alcohol. Obviously, avoidance is important, although there may be genetic predispositions in both mother and fetus. Certain maternal diseases predispose to arthrogryposis in the fetus, including maternal myasthenia gravis and maternal antibodies to fetal neurotransmitters (21). Steroid therapy seems to improve fetal outcome when there are maternal antibodies to fetal neurotransmitters (21,91,92). Finally, several inborn errors in metabolism in the fetus can lead to arthrogryposis (glycogenosis type VII; phosphofructokinase deficiency; ARC; and metabolic situations leading to edema, such as storage disorders). *In utero* therapy for some of these may be available in the future.

Early initiation of physical therapy and splinting to stretch affected joints (rather than initial casting) has markedly improved outcomes, and led to less atrophy of the muscle that is present. Treatment often requires orthopedic intervention (37–50), etc. During surgery, seizures (36,653) and malignant hyperthermia may occur (35,56).

## 161.3 DIFFERENTIAL DIAGNOSIS

The differential diagnosis of multiple congenital contractures is extensive. Tables 161-2–161-6 outline most of the more common conditions to consider. Tables 161-9 and 161-11 through Table 161-18 may help identify disorders to consider. Table 161-10 lists conditions known to often have multiple congenital contractures; however, either due to limitation in space or knowledge, they are only listed. Overall, 5–10% of cases of arthrogryposis have been considered to be myopathic (58,98) and 90–95% to be neuropathic (58). However, recently many muscle proteins have been found to be involved in conditions previously thought to be neuropathic, such as the distal arthrogryposes (86,99–105a,106). The neuropathic group include amyoplasia, the etiology for which is unclear. With true malformations of the CNS and with *in utero* disuse, muscle biopsies may appear neuropathic. However, if a myopathy or end-plate abnormality occurs early in the *in utero* development, there may be retrograde loss of the developing neuron. Thus pathologic changes can be confusing. Many specific conditions can be recognized by particular clinical features and/or by laboratory tests.

The clinical approach found to be most useful has been to first distinguish three categories of congenital contractures on a clinical basis: (i) primarily limb involvement; (ii) musculoskeletal involvement plus other system malformations or anomalies; and (iii) musculoskeletal involvement plus lethality, CNS dysfunction, and/or significant mental retardation/mental disability. Tables 161-2–161-4 are organized on the basis of this clinical approach. In addition, there is a table (Table 161-6) on maternal illness and exposure. Table 161-5 represents some of the many chromosomal anomalies, including microdeletions and duplications,

TABLE 161-2 Primarily Limb Involvement							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Absence of finger prints	136000 612761	Absent dermal ridges Mild webbing Congenital milia Dystrophic dry skin	Fingers Toes	Flexed Camptodactyly	Milia: transient (disappear at 6 months)	Chromosomes: normal Skin biopsy: normal	AD <i>SMARCAD1</i> at 4q22
Absence of DIP creases		Absent DIP creases Palmar contractures	Fingers Hands	Camptodactyly Flexed	Progressive	Radiographs: no bone fusion Chromosomes: normal	AD
Amyoplasia (see also transient neonatal arthrogryposis)		Loss of muscle tissue and replacement with fat and fibrous tissue Usually symmetrical contractures, always equinovarus feet and extended elbows Round face, midline capillary malformation Normal intelligence Abdominal wall defects and bowel atresia (10%) Increased in one of monozygous twins	Wrists Elbows Shoulders Hips Knees Feet	Flexion Extension Internal rotation Flexion, ± CDH Extension or flexion Equinovarus	Improves with therapy Usually need surgery Normal IQ Classically symmetric with all four limbs involved Some individuals have only arms or legs involved	Spinal cord: decreased size of anterior horn cells Muscle: variation in fiber diameter, small fibers, replacement of muscle with fat and connective tissue	Apparently sporadic with increase of anomalies related to vascular compromise
Angulation of long bone with overlying dimples and shortening of soft tissue		Angulation of long bones Dimple at apex of angulation Shallow flexion creases Short flexion tendon Short stature	Elbows Wrists Ankles	Limitation of dorsiflexion Limitation of extension Limitation of extension	Angle decreases Limited movement decreases	Radiographs: show bone angulation	AR
Antecubital pterygium (Shin Shun)	178200	Elbow dysplasia Antecubital web ± carpal wrists anomalies	Elbows ± Wrists	Carpal fusion Flexion	Nonprogressive	Radiographs: ± fusion of humerus and ulna, ± dysplasia of condyle, ± trochlear dysplasia	AD

TABLE 161-2    Primarily Limb Involvement—Cont'd							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Bruck syndrome (also see angulation of long bone and osteogenesis imperfecta: see Table 161-4)	259450	Osteoporosis and fractures	Elbows	Limitation of extension	Inability to walk	Normal collagen I studies	AR, consanguinity
	607063	Bowing of long bones			Decreased muscle strength		<i>PLOD2</i> mutations at 17p12
	609220	Scoliosis secondary to vertebral flattening and wedging anomalies; may lead to pulmonary restriction	Hips	Lateral rotation	Intramedullary rodding helps	Radiographs: bowing, osteoporosis, and wormian bones	<i>FKBP10</i> at 17q21.2
	610698	No blue sclera, deafness, or dentinogenesis	Knees	Flexion	Pulmonary function compromise	Cystic changes at fracture sites	Also linkage to 3q23–24
		Short stature	Ankles	Equinovarus	Increasing deformity		
		Hypermobility of small joints	Feet		Progressive thoracic kyphosis		
					Progressive webbing		
Camptodactyly (see also Table 161-3 and Table 161-13)	114200	Camptodactyly Not always present at birth	Fingers ± Toes	Flexion Flexion	May be progressive	Shortness of deep flexor tendons	AD
Camptodactyly with arthropathy	208250	Camptodactyly Joint effusions ± arthritis	Fingers Toes	Stiff Curved	Slowly progressive	Arthritis changes	AR
Clasped thumbs, congenital (see also adducted thumbs and clasped thumbs with MR, Table 161-4)	314100	Extensor muscles and tendons of thumb weak or absent	Thumbs (bilateral) Occasionally 1st finger	Flexion at MP and DIP joints Radial deviation	Surgical treatment, tendon transplant	Hypoplastic tendon Peripheral neuropathy	AD <i>PRG4</i> gene mutation at 1q25–q31
Coalition(s)	186400	Calcaneus–navicular	Ankles	Fusion ± Contractures		Radiographs: synostosis Differential diagnosis: peroneal spastic foot	AD Some related to 17q22
	186570	scaphoid–astragalus	Toes				
	186750	Talus–navicular					
	602991	Calcaneus–scaphoid					
Contractures, continuous muscle discharge, and titubation	160120	Contractures	Hands	Fixed	Worsening contractures	Abnormal muscle fibers	AD <i>KCNA1</i> at 12p13.3
	170260	Myokymia	Feet	Flexion	Pulmonary compromise		
		Ataxia Titubation	All extremities	Stiffened			

Distal arthrogryposis (type 1)	108120	Clenched hand with overlapping fingers at birth; opens to ulnar deviation (90%)	Fingers	Clenched, overlap, then open and ulnar deviation	Good therapy response, improves with time Variable within families	Radiographs: hip dislocation, mild scoliosis, misplaced or hypoplastic tendons	AD (variable) <i>TPM2</i> ( $\beta$ tropoysin) 9p11.3 <i>MYBPC1</i> at 12q23.2 <i>TNN12</i> at 11p15.5 <i>TNNT3</i> at 11p15.5
	160794	Usually calcaneovalgus, but all combinations (80%) of clubfeet Other major joint contractures	Knees	Often uninvolved			
	190990		Elbows	Often uninvolved			
			Ankles	Calcaneus valgus or equinovarus			
			Toes	Overlap camptodactyly			
Humeroradial synostosis (HRS)	143050 236400	Familial AD: 100% are bilateral AR: 91% are bilateral Sporadic: 62% have hypoplasia of hand and 77% have involvement of ulna	Elbow	Fixed	Surgery may improve function	Radiographs: humeroradial synostosis	46% are sporadic 38% are familial 25% are AR 50% are AD
Liebenberg syndrome (primarily upper limbs)	186550	Prominence of radial head Unusual slope of olecranon process Brachydactyly Stebломicrodactyly Intercarpal fusion and synostosis Dislocation of radial head	Mainly upper limb flexion contractures		Nonprogressive	Radiographs: fusion of triquetrum and pisiform	AD
<b>Lower Limbs Only</b>							
Lower limb only Amyoplasia		Only lower limbs involved Markedly decreased muscle Slightly short legs	Hips Knees Feet	May be dislocated Flexed or extended Equinovarus severe	Nonprogressive Responds to PT and surgery	Fibrous fatty replacement of muscle	Sporadic Increased in one of twins
Lower limb only arthrogryposis Fleury type (spinal muscular atrophy)	600175	Lower limbs only involved Lumbar lordosis Thoracic scoliosis $\pm$ kyphosis Muscle weakness or paralysis in lower limbs with wasting Absent reflexes No dimpling	Hips  Knees Feet	Flexion, subluxation Flexion Variable	Feet respond well to surgery Scoliosis progressive Nonprogressive limb involvement No fasciculations	Radiographs: spine – WNL or spina bifida occulta Blood and CSF chemistry: WNL EMG and nerve conduction: WNL Biopsy: variation in fiber diameter and fatty replacement CT scan: variable muscle size	AD Variable expression <i>TRPV4</i> at 12q23.24

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Lower limb only arthrogryposis (Ray/Sarralde type)	602484	Pelvic dysplasia Muscular hypotrophy of lower limbs Prenatal growth retardation, particularly lower segment Lumbar lordosis Winged scapulae Muscle hypoplasia in legs	Hip  Knee Feet	Pelvis hypoplastic with contractures Flexion Variable	Hypoplastic lower limb muscles Hypertrophy of neck and paraspinous muscles Continue to be below 5th in percentile height Feet resistant to therapy	Radiographs: pelvic dysplasia, small pelvic wings, acetabular dysplasia, iliac hypoplasia, notched acetabulae osteoporosis, vertebrae cuboid and wedged, slender long bones, lumbar lordosis Lab: WNL EMG: WNL, normal nerve conduction	AR, consanguinity
Meningomyelocele with spinal dysplasia	182940	Neural tube defects interfering with cord development		Variable lower limb congenital contractures		Can be diagnosed prenatally	Multifactorial Part of NTD spectrum
Lower limb only arthrogryposis, X-linked (type 6) (See also Kuskokwim syndrome Table 161-3)	301830	Thin tendons Lower limbs affected in males		Generalized flexion of lower limb	Lower limbs responsive to therapy Ambulatory with impaired gait Nonprogressive		X-linked, mapped to Xq23–27
Mesomelic dysplasia	156232	Short middle segment Coalitions of carpals and tarsals	Wrist Feet	Flexed Equinovarus	Able to function independently	Radiographs: bony fusion and short middle segment	AD Linked to 2q24–q32
Patella aplasia-hypoplasia (See also genitopatellar syndrome)	168860	Occasional congenital contractures Absent or small patellae			Functional	Radiographs: missing or small patellae	AD <i>PTLAH</i> gene mutation at 17q21–22

Poland anomaly	173800	Absent pectoralis major (costal head) Ipsilateral limb deficiency	Flexion contractures of affected arm		Nonprogressive	Radiographs: hypoplasia of missing or absent phalanges, rib deficiencies, synostoses	Sporadic, AR? Probably vascular
Radioulnar synostosis (RUS)	179300	Radioulnar synostosis Short forearm	Hand Elbow	Fixed in extension Limitation of movement	Nonprogressive	Radiographs: synostosis of proximal radius and ulna seen in chromosomal anomalies involving X and Y	Sporadic and AD
Saul–Wilson type skeletal dysplasia		Short stature Bone dysplasia Characteristic facies Seizures	Generalized flexion and limitation of movement Feet	Clubfeet	Nonprogressive	Radiographs: short phalanges with cone-shaped and sclerotic epiphyses, overtubulation of long bones, hypoplasia of vertebral bodies	
Symphalangism “Cushing” (see also multiple synostosis, Table 161-3)	186500 602991	Symphalangism of PIP joints Deafness variable Variable carpal and tarsal ankle bone fusion	Fingers Lower limbs	Fusions Clinodactyly Fusions of toes	Fusions and contractures become worse with time	Radiographs: PIP fusions ± DIP fusion, ± talus and navicular fusion	AD NOG at 17q21–22 GDF5 of 20q
Symphalangism distal	185700	Symphalangism of DIP joint Synostosis of metacarpals and metatarsals	Generalized limitation of movement of hands, feet, and limbs		Nonprogressive	Fusions of phalangeal bones	AD
Symphalangism/brachydactyly (see also multiple synostosis, Table 161-3)	113450	Brachydactyly Symphalangism (proximal and distal) ± Clubfeet ± Craniosynostosis ± Scoliosis just before menarche Deafness Missing distal fingers or nails	Hands Hips Feet	Limited movement Flexed Talipes equinovarus	Nonprogressive	Lab data normal Radiographs: carpal fusion ± Flat vertebrae ± craniosynostosis	AR AD

**TABLE 161-2**   **Primarily Limb Involvement—Cont'd**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Symphalangism/brachydactyly, Nievergelt–Pearlman type	163400	Radioulnar synostosis Coalitions in tarsals and carpals Symbrachyphalangism of fingers	Hands Elbows  Feet	Clinocamptodactyly Radioulnar synostosis Talipes, tarsal synostoses	Nonprogressive	Radiographs: radioulnar synostoses, carpal and tarsal synostoses	AD
Transient neonatal arthrogryposis		Flexion contractures Muscles firm and rigid	Generalized flexion contractures, except elbows usually extended		Contractions resolve over first week  Muscles then become normal texture	Elevated muscle enzyme and WBC count	Sporadic
Vertical tibial crease syndrome		Vertical crease down anterior shin, usually bilateral	Generalized flexion contractures		Nonprogressive Responsive to therapy Half have DD		AR
Upper Limb Only (See also Table 161-3 and Liebenburg syndrome)							
X-linked resolving arthrogryposis	301830	Flexion contractures Camptodactyly Anterior rotation of shoulders	Generalized flexion contractures Feet	Flexed ankle	Resolving		X-linked

Presented by: <https://jafrin>

AD = autosomal dominant; AR = autosomal recessive; CDH = congenital dislocation of the hip; CSF = cerebrospinal fluid; CT = computed tomography; DIP = distal interphalangeal; EMG = electromyography; FDS = flexor digitorum superficialis; FPL = flexor pollicis longus; PIP = proximal interphalangeal; WBC = white blood cell; WNL = within normal limits.

TABLE 161-3 Musculoskeletal Involvement Plus Other System Anomalies							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Aase–Smith syndrome (see also distal arthrogryposis with ophthalmoplegia DAV/2B)	147800	Camptodactyly Dandy–Walker malformation Agenesis of corpus callosum Hydrocephalus Cleft palate Scoliosis Thin fingers with hypoplastic dermal ridges Mild craniofacial features	Hands Elbows Knees Hips Feet	Flexion Usually flexion Flexion or extension Flexion Equinovarus	Nonprogressive except one died as newborn	Autopsy: neuroblastoma, ventriculoseptal defect	AD
Alkuraya arthrogryposis syndrome (Perthes and ophthalmoplegia, see also distal arthrogryposis DA5/2B)	614051	Ophthalmoplegia (downward gaze) Congenital heart disease Perthes of femoral heads Pyloric stenosis	Generalized flexion contractures		Progressive hip disease Develop loose joints	MRI of eye and brain within normal limits X-rays: collapse of epiphyseal of femoral head	AR
Camptodactylies							
Camptodactyly, arthropathy, coxa vara, pericarditis, synovitis (ARC)	208250 604283	Thickened synovia Pericarditis Distal contractures	Fingers  Knees Hips	Camptodactyly  Flexion contractures Flexion	Progressive contractures Thickening of synovia Pericarditis may be lethal Swelling of joints progressive	Biopsy: hyperplasia of synoviocytes, hyperplasia of pericardium	AR <i>PRG4</i> at 1q24–q25
Camptodactyly, Guadalajara (two types)	211910	Camptodactyly Short stature IUGR Microcornea Microphthalmia Microcephaly, MR Pectus excavatum	Hands  Hips Feet	Flexion  Dislocated Equinovarus	Nonprogressive	Radiographs: dislocated hips, scoliosis	AR
Camptodactyly, Kilic (see also distal DAV/2B)	602612	Camptodactyly Myopia Fibrosis of medial rectus Mild scoliosis Ptosis High palate	Fingers  Knees Feet	Camptodactyly  Flexion Pes caves	Progression, functional	Radiographs: coalition of carpals	AR

**TABLE 161-3    Musculoskeletal Involvement Plus Other System Anomalies—Cont'd**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Camptodactyly, London	211965	Camptodactyly	Fingers	Flexion, ulnar deviation	Nonprogressive		AR
		Facial immobility	Feet	Vertical talus			
		Ichthyosis					
		Short stature					
		Scoliosis					
Camptodactyly, Tel Hashomer	211960	Camptodactyly	Fingers	Spindle shaped	Nonprogressive	Muscle hypoplasia, type 2b fibers	AR
		Long, thin nose with high, broad bridge; prominent forehead	Toes	Contractures		Mild skeletal changes	
		Short stature					
		Scoliosis					
		Cardiac anomalies					
Caudal deficiency and asplenia (see also maternal diabetes)		Caudal deficiency	Hips	Flexion	Nonprogressive	Radiographs: absent sacrum, dextrocardia	Some are X-linked
		Asplenia	Knees	Flexion			
		Agenesis/hypoplasia of corpus callosum					
		Meningomyelocele					
		Cardiac anomalies					
Congenital fiber type disproportion with congenital contractures (most cases of arthrogryposis have fiber disproportion from disuse)	102610	Generalized contractures	Distal flexion contractures		Nonprogressive	Often related to disuse	Sporadic AR
	255310	Disuse atrophy					
							<i>ACTA1</i> at 10q24
Conradi–Hünemann syndrome (chondrodysplasia punctata)	300205	Hypertelorism, prominent forehead	Generalized flexion contractures		Deformities may increase	Radiographs: punctuate calcifications, tubular bones mildly short, scoliosis – abnormal vertebrae	AD; X-linked dominant lethal in males
	302960	Cataracts (17%)	Feet	Talipes equinovarus			
		Limb contractures (27%)					
		Patchy skin –Atrophoderma –Follicularis/alopecia					
					Boney changes lead to progressive scoliosis	Pathology: epiphyses abnormal	<i>EBP</i> at Xp11p33
Contractural arachnodactyly	121050	± Congenital heart anomalies	Generalized flexion contractures		Improves with age (knees the worst)	Radiographs: bones gracile, kyphoscoliosis, advanced bone age	AD
	612570	Chest deformities	Elbow	Limitation of supination and pronation			
		Long thin limbs			About 10% get worse with age		
		Generalized contracture	Feet	Dorsiflexion			
		Crumpled ear					<i>FBN2</i> mutation at 5q23–31
							12q13

Presented by: <https://jafrlibrary.org>

Diastrophic dysplasia	222600 606718	Dwarfism with contractures Joint contractures Hitchhiker thumb becomes fused Scoliosis/vertebral instability Abnormal ears Cleft lip and palate ± Abnormal tracheal ring	Thumbs  Fingers  Hips Feet	Adducted  Ankylosed at PIP joint Dislocated Severe talipes equinovarus	Progressive (probably due to joint trauma) Fusion of many joints Calcium deposits throughout	Radiographs: precocious calcification of cartilage Pathology: abnormal epiphyses, hypertrophic auricular cartilage and calcifications, specific histology	AR <i>SLC26A2</i> at 5q31
<b>Distal Arthrogryposes</b> (See also Gordon syndrome DAI, Table 161-2, Table 161-4)							
Distal arthrogryposis with deafness and camptodactyly (Bamshad type 6)	602782	Sensorineural deafness Camptodactyly without fusion Proximally placed thumbs Dry skin	Generalized flexion contractures		Nonprogressive	Muscle mass decrease distally Histiocytosis	AR check correct location <i>CATSAL</i> , <i>CATSH</i> at 11q25
Distal arthrogryposis with facial involvement (Sheldon–Hall, Bamshad type 2B)	160720 190990 191043 600692 601680	Down-slanting palpebral fissures Prominent chin Small mouth Cervical webbing Variability in family	Generalized flexion contractures		Nonprogressive Functional hands Ambulatory		AD fast twitch muscle apparatus <i>TNNT3</i> at 9q21 <i>TNNI2</i> at 11p15 <i>TNNT3</i> at 11p15.5 <i>MYH3</i> at 17p13
Distal arthrogryposis, ophthalmoplegia, and firm muscles (Hall type IIB, Bamshad type 5)		Firm muscles Ophthalmoplegia Deep-set eyes Ptosis Stiff spine Decreased facial expression Short stature	Generalized contractures in flexion Usually talipes equinovarus		Progressive, particularly pulmonary restriction Ophthalmoplegia which may develop over time Ambulatory, remains stiff Muscle firm	Muscle biopsy; ragged red fibers, disuse atrophy	AD One family with retinitis pigmentosa and MR
Distal arthrogryposis with cleft lip/palate (Hall DA IIC)		Distal contractures Cleft lip ± palate variable in family members	Generalized flexion contractures Feet	In various positions	Responds to therapy		AD

**TABLE 161-3    Musculoskeletal Involvement Plus Other System Anomalies—Cont'd**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Distal arthrogryposis with scoliosis (Hall type 2D, Bamshad type 4)	609128	Distal contractures Severe scoliosis ± vertebral anomalies	Fingers Feet Back	Clenched Variable Stiff and scoliotic	Scoliosis Progressive	Occasional hemivertebrae	AD
Distal arthrogryposis with trismus (Hall type DA IIE may be part of amyoplasia spectrum) DA Type 7B	121070	Distal contractures Trismus Mild MR in 1/3	Generalized flexion contractures Hands  Feet	Wrist flexion, MCP extended, fingers flexed Variable	Responds to therapy Jaw often continues to have limitation		Sporadic Seen in one of MZ twins May often have vascular compromise
Distal arthrogryposis Shalev type, mainly uppers DA Type 16		Ptosis Arched eyebrow Webbing of neck 65% Brachydactyly Umbilical hernia Decreased facial movement	Upper limbs flexion contractures Hands Elbow  Lower limbs less frequent 35%  Knee Foot	flexion contractures Camptodactyly Flexion contractures   Extended Clubfoot, vertical talus	94% nonprogressive		AR
Distal arthrogryposes absent teeth, distinct face DA Type 13		Absent bicuspid teeth Otosclerosis Depressed coronal suture Broad nose Long philtrum Short stature	Generalized flexion contractures Fingers  Feet	flexion contractures Camptodactyly, adducted thumb Camptodactyly and bunion	Progression of contractures ADHD		AD
Duane's retraction syndrome and multiple contractures (see DA IIB/5)		Inability to abduct eye Narrow of palpebral fissure	Generalized flexion contractures		Nonprogressive		Mainly sporadic
Dundar–Sonada distal arthrogryposis	601776	Hypertelorism MR Blepharophimosis Down-slanting palpebral fissures Arachnodactyly Renal anomalies Cardiac anomaly Broad forehead	Hands Generalized flexion contractures Feet	Adducted thumbs Clubfoot	Nonprogressive	Hydronephrosis	TARP at AR

Ectodermal dysplasia with contractures	601701	Dry skin Hyperkeratosis Sparse hair, pili torti ± Cataract Brittle nails Enamel anomalies Enlarged joints	Hands Generalized flexion contractures Feet	Camptodactyly Generalized flexion contractures Equinovarus	Short stature Normal development Develop diabetes Develop scoliosis		AR Consanguinity
Ectodermal dysplasia and cleft lip/palate with contractures		Blepharophimosis Cleft lip and palate Micrognathia Sparse hair Nail hypoplasia Developmental delay Glandular hypospadias Dental abnormalities	Fingers Generalized flexion contractures Hips Feet	Camptodactyly Dislocation Metatars adductus	Developmental delay Small but WNL Develop hyperopia and amblyopia Delayed dental eruption		
Ectodermal involvement, caudal appendage with contractures		Absent primary teeth Caudal appendage Slow-growing hair Ocular hypertelorism, blepharophimosis Bulbous nose Broad gums Shield chest	Generalized flexion contractures		Secondary teeth appear late	Radiographs: wormian bones Chromosomes: normal	Consanguinity
Ehlers–Danlos VIII	13008	Arachnodactyly Periodontitis Arthropathy Hyperextensible Aortic and mitral regurgitation Skin wrinkling and striking atrophic scars	Mild generalized flexion contractures		Progressive arthropathy and loss of teeth		AD 12p13 linkage
Ehlers–Danlos-like VIB-2	601776 608429	Progressive laxity of skin and joints Arthropathy Straight spine	Hands Feet	Adducted thumbs Clubfeet	Progressive arthropathy and contractures		AR <i>CHST14</i> at 11p
Focal femoral dysplasia (included femoral facial syndrome, FFS, FH, UHS)	134780	Cleft palate, long philtrum, short nose with hypoplastic alae nasi, micrognathia Shortened limbs: lower > upper Renal anomalies ± Unusual facies	Elbows Femur Hips Feet	Fixed in flexion Shortened flexion Dislocated Variable	Nonprogressive	Vertebral anomalies	Sporadic (associated with maternal diabetes)

TABLE 161-3 Musculoskeletal Involvement Plus Other System Anomalies—Cont'd							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Freeman–Sheldon syndrome (craniocarpotarsal dystrophy; whistling face syndrome; see also distal arthrogryposes DA-2)	193700 601680	Pursed lips, small mouth Cleft palate Immobile face, ptosis Contractures with ulnar drift Notched alae nasi “H” on chin Scoliosis	Hands  Hips Feet	Flexion with ulnar deviation Dislocated Calcaneovalgus	Nonprogressive Displaced tendons Fibrotic facial muscles		AD <i>MYH3</i> at 17p13 ?AR form
Gordon syndrome (Hall type IIA, Bamshad type 3) (see also distal arthrogryposes)	114300 193700	Distal contractures Cleft palate (40%) Ptosis Short stature Variable in families	Hands  Feet	Clenched, overlapping fingers Variable, calcaneovalgus or equinovarus	Respond well to therapy		AD <i>MYH3</i> at 17p13
Hand–foot–uterus syndrome	140000 142959	Contractures of hands and feet Coalitions Small thumbs and great toes Structural anomalies of uterus, particularly duplication	Hands Feet	Camptodactyly Talipes equinovarus	Nonprogressive	GU anomalies including renal	AD <i>HOXA13</i> at 7p15.2
Hanhart syndrome (aglossia adactyl/hypoglossia/hypodadylia)	103300	Limb deficiency with transverse loss Small or absent tongue ± Möbius sign Fusion of knee or elbow joints	Hands Elbows Knees Feet	Fused digits Fused Fused Fused digits	Nonprogressive		Sporadic, probably vascular
Holt–Oram syndrome	142900 601620	Abnormalities of shoulders, hands, and wrists Cardiac defects (structural) Abnormal joint structure (rare)	Hands Knees Feet	Usually hypoplasia, synostosis Flexed Talocalcaneal synostosis	Nonprogressive	Pathology: congenital heart defects, particularly septal, lung agenesis	AD <i>TBX5</i> at 12q24
Hoepffner syndrome	233805	Characteristic facial features with pinched, beaked nose Slim hands Mild pectus excavatum	Large joint flexion contractures		Nonprogressive	Abnormal lipids and cholesterol, reduced stimulation of RNA synthesis	AR
Juvenile hyaline fibromatosis (see Poretic–Murray syndrome)							

Presented by: <https://africabrary.org>

Knies dysplasia	120140 156550	Short-trunk dwarfism Short stature Kyphoscoliosis Joint enlargement with limitation Myopia, deafness, cleft palate	Generalized flexion contractures		Progressive weakness	Lab: some with high keratin sulfate excretion Radiographs: irregular ossification of epiphyses	AD, heterogenous <i>COL2A1</i> at q13
King–Denborough syndrome, includes Lumbee (see also multiple pterygium syndrome with hyperthermia, Table 161-3)	145600 180901 255993	Noonan-like facies with ptosis Webbed neck Kyphosis, scoliosis Cleft palate – high arch Pterygium with progressive weakness Malignant hyperthermia Seizures Pectus excavatum Cryptorchidism	Generalized flexion contractures Hips Feet	Dislocated Talipes equinovarus	Does respond to therapy Beware of anesthesia Progressive trunk deformities May have MR	Muscle biopsy does not always show myopathy CPK: high, low, or normal Several families have central core myopathy	AR Linked to genes for malignant hyperthermia <i>RYR1</i> at 19q13.3 <i>MHS3</i> at 17q
Kuskokwim syndrome (see also lower limbs only distal arthrogryposis, Table 161-2)	208200	Multiple joint contractures ± Pigmented nevi ± Corneal reflexes Normal intelligence	Elbows Knees  Feet	Flexed ± webs Flexed, fixed with webs Various positions		Pathology: muscle atrophy Radiographs: ± patella migration Normal muscle and nerve function	AR <i>FKBP10</i> at 17q21.2
Larsen syndrome	150250 (AD) 245600 (AR) 603381 606374 613165	Prominent forehead, hypertelorism, depressed nasal bridge, flat round face Multiple joint dislocations, particularly anterior knees, elbows Hand anomalies: long cylindrical fingers, broad at end Scoliosis ± vertebral anomalies Short stature ± Cleft palate ± Midcervical kyphosis/subluxation Cardiac septal defects Laryngeal and tracheal collapse	Generalized flexion contractures		Diminished cartilage Rigidity at birth, improves with time Continue to subluxate many joints	Radiographs: dislocated patella, poor ossification of phalanges, CDH, extracalcaneal accessory bone, hypoplasia of humerus distally †, carpal ossification, cervical vertebral subluxation Hydrocephalus	AR more severe <i>IMPAD1</i> at 8q12.1 <i>CANT1</i> at 17q25.3 <i>DTDST</i> at 5q32 AD <i>FLNB</i> at 3p14.3 <i>COL7A1</i> at 3p21.31 <i>B3GAT3</i> at 11q12.3

TABLE 161-3 Musculoskeletal Involvement Plus Other System Anomalies—Cont'd							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Marfan syndrome (severe neonatal)	134797	Marfanoid body habitus	Generalized flexion contractures		Usually lethal	One case homozygous for fibrillin 1 mutation	<i>FBN1</i> at 15q21 New mutations
	154700	Aortic incompetence Micrognathia Anterior chest deformity Pulmonary emphysema Ocular abnormalities Hypermobility fingers					
MASP mutations (3 M syndrome, Carnevale syndrome)	265050	Blepharophimosis	Hands	Camptodactyly		X-rays coalitions and synostosis	AR <i>COLEC11</i> at 2p25.3 <i>MASP1</i> at 3q27
	600521 612502	Ptosis Cleft lip and palate Deafness Developmental delay Craniosynostosis Congenital heart disease Radial ulnar synostosis Caudal appendage Omphalocele Diaphysis rectus	Hips Back	Dislocated Scoliosis			
Metaphyseal dysplasia (Jansen)	156400	Small thorax	Generalized flexion contractures		Progressive	Radiographs: hypercalcemia, hyperostosis of calvaria, lack of metaphyseal ossification gives gross irregular cyst-like areas	AD <i>PTHR</i> at 3p27.3
	168468	Characteristic facies Flexion joint deformities Wide, irregular Short stature					
Metatropic dysplasia	156530	Disproportionate short stature	Generalized flexion contractures		Progressive changes from epiphyseal dysplasia to metaphyseal dysplasia  Spinal changes severe	Radiographs: platyspondylia, kyphoscoliosis, pelvic hypoplasia, short limbs – metaphyseal flaring, epiphyseal irregularity, hyperplastic trochanters	AD? AR <i>TRPV4</i> at 12q24
	605427	Kyphoscoliosis Prominent joints with restricted mobility, but ± finger extensibility Pelvic hypoplasia					
Möbius syndrome	157900	Facial diplegia (Vth and VIth nerves)	Hands	Camptodactyly	Nonprogressive	EMG: frontalis orbicularis oculi, facial and external rectus – no response  Pathology: muscle hypoplasia and absent muscle	Most sporadic Also linked to 13q12.2–q1
		Joint contractures, reduction anomalies Difficulty swallowing Chest and trunk: absent muscles (e.g., pectoralis muscle)	Knees Feet	Flexed Talipes equinovarus			

Multiple pterygium syndrome (Escobar type) (See also maternal antibodies against neurotransmitters receptors)	100730 253290 265000	Multiple webs develop over time Cryptorchidism Vertebral anomalies ± scoliosis ± cleft palate Deafness Eyelids: antimongoloid slant, ptosis Progressive thoracic lordosis Restrictive lung disease Short stature	Generalized flexion contractures  Fingers Hips Feet	  Camptodactyly with hyperextensibility Lumbar lordosis Rockerbottom or calcaneovalgus	Two forms: nonprogressive and progressive Pterygia increase with time Camptodactyly quite functional Finger webs develop	Pathology: skin, spinal cord, and brain normal Muscle hypoplasia, fatty replacement; Progressive respiratory dysfunction	AR <i>CHRNA1</i> at 2q37 <i>CHRNA1</i> at 2q24–32 <i>RAPSN</i> <i>DOK7</i> at 4p16.3
Multiple pterygium syndrome (autosomal dominant)	178110	Pterygium across large joints	Generalized flexion contractures with multiple webs Camptodactyly		Fairly functional		AD
Multiple pterygium and malignant hyperthermia syndrome (see also King–Denborough syndrome, Table 161-3)	217150	Decreased facial movement Neck webs Crouching stance Scoliosis	Generalized flexion contractures		Respond to preventative treatment Progressive scoliosis Monitor during anesthesia for possible malignant hyperthermia episodes	Low CPK Biopsy for muscle pathology	AR <i>RYR1</i> ?
Multiple synostosis (severe symphalangism, WL syndrome; also see synphalangism)	186500 601146	Symphalangism Deafness from ossicular fusion – progressive Long nose with broad bridge Synostosis of elbows Coalition of tarsals and carpals Distal digit defects	Generalized fusion and flexion contractures		Increasing fusions Progressive deafness	Fusion of bones, hemivertebrae, fixed ossicles	<i>NOG</i> at 17q21–22 Also <i>GDF5</i> at 20q.11.2 <i>FGF9</i> at 13q11q12
Nail–patella syndrome (hereditary onycho-osteodysplasia) (see also absent patella and genitopatella syndromes)	161200 602575	Nail dysplasia Absent or hypoplastic patella Joint contractures ± kidney disease Occasional elbow and knee webbing Glaucoma Dislocation radial heads	Generalized flexion contractures Fingers Feet	Ulnar deviation Pes Planes, talipes equinovarus	Nonprogressive except renal disuse	Radiographs: pathognomonic iliac horns, absent patella, subluxation of radial heads	AD <i>LMX1B</i> at 9q34 Renal failure (nephritis) mapped to 9q34 and <i>COL1A5</i>

**TABLE 161-3    Musculoskeletal Involvement Plus Other System Anomalies—Cont'd**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Nemaline myopathy (see central core and Table 161-4 myopathies)	161650 256030	Hypotonic Respiratory problems Congenital heart disease Short 1st metacarpal Adducted thumbs Micropenis	Generalized flexion contractures Feet	Talipes equinovarus		Autopsy and biopsies shows nemaline bodies	AR <i>NEB</i> at 2q21.2–22ACTA at 1q42.1
Neurofibromatosis	162200 613113	Neurofibromas Café-au-lait spots (multiple) Congenital contractures ±	Generalized flexion contractures		Can be progressive	Histopathology: neurofibromas When contractures often CNS structural abnormality	AD <i>NF1</i> at 17q11–q12 New mutations frequent
Neuropathic Israeli–Arab arthrogryposis	208100	Marked variability in family Hypoplastic muscles around affected joints ± CHD	Generalized flexion contractures Feet	Talipes equinovarus	Individuals with mild symptoms cope well Most adults are employed Normal intelligence	Marked decreased nerve conduction	AR Mapped to 5q33 (near <i>SMN</i> ) Females less affected than males
Nevo syndrome (see also Ehlers–Danlos VIA)	153454 601451	Kyphosis Hyperbilirubinemia Hypotonia Prominent forehead Hyperlordosis Cervical spine Cryptorchidism	Feet Generalized flexion contractures	Talipes	Increasing laxity	MRI: myopathic changes	<i>PLOD1</i> at 1p36.22
Oculo–dento–digital syndrome	121014 164206	Small sunken eyes Thin nose Severe hypoplasia of enamel, microdontia Phalangeal hypoplasia, camptodactyly of 4th and 5th digits Syndactyly Microphthalmia	Fingers Feet	Camptodactyly Hallux abductis		Chromosomes: normal Radiographs: absence of middle phalanges of toes, widening of long and short tubular bones and ribs and clavicles, metaphyseal changes, white matter changes in CNS	AD <i>GJA1</i> at 6q21–q23.2

Oral–canial–digital syndrome (Juberg–Hayward syndrome)	216100	Cleft lip and palate Hypoplastic, inflexible, distally placed thumbs Bilateral elbow deformities Microcephalus, mild MR Pituitary dysfunction Prominent forehead	Thumbs Elbows  Toes Renal anomalies	Inflexible Limited extension, dislocated radial heads Camptodactyly		Radiographs: 1st metacarpals small, radius dislocated, vertebral anomalies Chromosomes: normal Low growth hormone	AR
Parastremmatic dysplasia	168400 605427	Multiple contractures Twisted legs Bowed long bones Kyphoscoliosis	Elbows Hips Knees Elbows  Feet	Flexed Flexed Dislocated ± Radioulnar synostoses ± Calcaneovarus	Slowly progressive	Radiographs: coarse trabeculations, dense “flocked wool” areas, lacy border to pelvis	AD <i>TRPV4</i> at 12q24
Pfeiffer cardiocranial syndrome (FGFR syndrome)	101600 136350 176943	Craniosynostoses, brachycephaly, syndactyly ± Contractures ± Humeroradial synostosis CHD Often webbing	Generalized flexion contractures Thumb	Adducted and broad		Radiographs: broad distal phalanges	AD <i>FGFR1</i> at 8p11.23 <i>FGFR2</i> at 10q26
Popliteal pterygium syndrome (facio–genital–popliteal, Gorlin type)	119500 607199	Popliteal web with cord at edge Cleft palate, cleft lip, lip pits, frenula, intraoral web, ± ankyloblepharon Syndactyly Nail anomalies; absence, deformities of digits Short stature Genitals with web and scrotal anomaly	Knees Feet	Flexion with webs Equinovarus	May require surgery to release – watch for nerve and vessel in web	Pathology: free edge of web is cord-like and web contains sciatic nerve and blood vessel Variable within family	AD <i>IRF6</i> at 1q32.2
Proteus syndrome with distal arthrogryposis	164730 176920	Hamartoses Congenital lipomas Lymphangiomas and hemangiomas Hemihypertrophy Skin anomalies	Fingers  Elbows Feet	Camptodactyly with ulnar deviation Flexion Metatarsus varus	Patchy overgrowth Hemihypertrophy Improving contractures Variable Sudden death	Quite variable pathology of tumors	AD Mainly new mutations <i>AKT1</i> at 14q32.3

**TABLE 161-3    Musculoskeletal Involvement Plus Other System Anomalies—Cont'd**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Puretic–Murray syndrome (juvenile hyaline fibromatosis)	228600 608041	Joint contractures Face/skull deformities Gingival hypertrophy Multiple fibromatosis Skin lesions Infections: skin, eyes, nose, ears Other tumors	Generalized flexion contractures		Progressive contractures from early infancy with pain	Histopathology: skin ↑ collagen, ↑ soluble protein, tumors, ↑ fat content, altered connective tissue	AR <i>CMG2</i> or <i>ANTX</i> at 4q21
Rigid spine muscular dystrophy (also see stiff man/stiff baby Table 161-3)	602771 606210	Stiff spine Dislocated radial heads Feeding problems Heart failure related to RVH Scoliosis Bilateral diaphragmatic and inguinal hernias	Elbows  Neck Ankles	Limitation of movement Flexion Limitation of movement	Not progressive, however respiratory failure and heart failure	Myopathic muscle biopsy Cytoplasmic bodies Mini multicore myopathy EMG: exaggerated response	AR Consanguinity <i>SEPN1</i> at 1p36
Sacral agenesis	142994 Rarely 176450	Lower limb aplasia with contractures ± Others	Shoulders Hips Feet	Sprengel deformity Flexion Talipes equinovarus		Presacral tumor Radiographs: absence of sacrum Mostly due to maternal diabetes Bony abnormalities in 1% of diabetic mothers	Mostly sporadic Currarinio syndrome (AD) <i>MNX1</i> at 7q36
Schwartz–Jampel syndrome	142461 255800	Small stature Myotonia Fixed facial expression, pinched; pursed lips, small mouth Contractures; pectus carinatum Blepharophimosis Myopia Normal intelligence	May have generalized flexion contractures		Progressive: very mild at birth, gets worse during childhood  Variable expression: the worse the bony changes, the worse the progression	EMG: characteristic myotonic pattern Flattened epiphyses Dislocated radial head	AR <i>HSPG2</i> at 1p36
Spondyloepiphyseal dysplasia congenita	120140 183900	Short trunk Myopia Lag in epiphyseal mineralization including vertebrae Deafness	Elbows Hips Knees	Joint limitation Dislocation Flexion contractures	Progressive	Radiographs: flat epiphyses, ± mineralization of pubis, talus, calcaneus, knee centers, flat vertebrae	AD <i>COL2A1</i> at 12q13.11

Stiff man/stiff baby syndrome (see also rigid spine, Table 161-3)	138491 138492 184850	Alert, tense facial expression Hiatal, diaphragmatic, and umbilical hernias Feeding problems Intermittent generalized contractures	Generalized flexion contractures		Improves	EMG: exaggerated response	AD <i>GLRA1</i> at 5q33 and <i>GLRB</i> at 4q32.1 and antibodies against the
Trismus pseudo-camptodactyly syndrome (Dutch Kentucky syndrome, Hecht Beals syndrome)	158300 160741	Trismus, inability to open mouth fully Limited movement of fingers when wrist dorsiflexed Dislocated hips Generalized contractures Short stature	Jaw Fingers Hips Feet	Tight Camptodactyly Dislocated Varus	Nonprogressive	Pathology: shortened flexor tendons TMJ abnormally flat	AD <i>MYH8</i> at 17p12–p13
Tuberous sclerosis	191092 191100 605284	Glioma–angioma lesions, phacomata Seizures Adenoma sebaceum, ± shagreen patch Pigment and depigmented patches ± Joint contractures Cardiac and renal tumors	Fingers Feet Toes	Camptodactyly Equinovarus Camptodactyly	Can be progressive	Autopsy: brain – tuberous sclerosis lesions Radiographs: no bone changes	AD Variable, most without contractures <i>TSC1</i> at 9q <i>TSC2</i> at 16q
Ullrich congenital muscular dystrophy	120250 254090	Weakness Hypotonia, motor delay Proximal contracture Distal hyperextensibility Scoliosis, torticollis Rough skin	Shoulders Elbows Hips Knees Ankles	Tight Flexion Dislocated Flexion Flexion	Progressive	MRI: CNS normal EMG: myopathic Muscle biopsy: dystrophic and sclerotic	AR AD <i>COL6A3</i> at 2q33 <i>COL6A1</i> at 21q22.3 <i>COL6A2</i> at 21q22.3
VATER association	192350	Vertebral/vascular defects Anal atresia TE fistula Esophageal atresia Radial/renal defects	Hands Arms Leg	Camptodactyly Flexion contractures Flexion contractures		Chromosomes: normal Pathology: CHD, anal atresia, TE fistula, renal anomaly	Mostly sporadic <i>HOXD13</i> at 2q31.1
Van den Ende–Gupta syndrome	600920 613619	Blepharophimosis Arachnodactyly Prominent forehead Triangular face Skeletal anomalies Hypoplastic alae nasi Microstomia, beaked nose Large ears Everted lower lip	Generalized flexion contractures Short stature Dislocated radial head Fingers Toes	Camptodactyly Camptodactyly	Nonprogressive Self-limited contractures	Mild skeletal changes Bowed long bones	AR Consanguinity <i>SCARF2</i> at 22q11.21

**TABLE 161-3 Musculoskeletal Involvement Plus Other System Anomalies—Cont'd**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Waardenburg–Klein syndrome (WS3)	148820 606597	White patch or early graying hair Pigmentary anomalies Blepharophimosis Deafness Displaced inner canthus Heterochromia of the iris Syndactyly and finger contractures Carpal fusions	Generalized flexion contractures Fingers Wrists Elbows	Camptodactyly Flexion Flexion	Nonprogressive	Neural crest anomaly	AD <i>PAX3</i> at 2q35–q37.1
Weill–Marchesani syndrome	277600 608990	Short stature Stiff joints Carpal tunnel Small/dislocated lenses	Generalized flexion contractures Fingers	Camptodactyly	Slowly progressive	Carpal and tarsal tunnels from excessive connective tissue	AR <i>ADAMS10</i> at 19p13.3–p13.2
Winchester syndrome	259600 120360	Craniofacial asymmetry and coarsening Brachydactyly and contractures Faint corneal opacities Malar flush, thick facial skin Osteoporosis Gum thickening Arthropathy	Generalized flexion contractures		Progressive	Lab: not MPS Pathology: swelling and degeneration of mitochondria, dilation of endoplasmic reticulum, osteolysis of tarsals, osteoporosis	AR <i>MMP2</i> at 16p11.2
X-linked arthrogryposis, moderately severe (type 3)	301830	Generalized contractures Dimples over shins Small mouth May have mild MR	Generalized flexion contractures		Slowly improves	Short hypoplastic tendons	X-linked recessive Xp11.3–q11.2

Ach = acetylcholine; AD = autosomal dominant; ADHD = attention deficit/hyperactivity disorder; AR = autosomal recessive; CDH = congenital dislocation of the hip; CHD = congenital heart disease; CK = creatine kinase; CPK = creatine phosphokinase; EMG = electromyography; GU = genitourinary; IUGR = intrauterine growth restriction; MCP = metacarpophalangeal; MPS = mucopolysaccharidosis; MR = mental retardation; MRI = magnetic resonance imaging; MZ = monozygotic; PIP = proximal interphalangeal; TE = tracheoesophageal; TMJ = temporomandibular joint.

**TABLE 161-4     Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Le**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Acrocallosal syndrome (see also Aicardia– Goutières syndrome)	200900 611254	MR Agenesis corpus callosum Dandy–Walker malformation Postaxial polydactyly Duplication of hallux Hypertelorism Macrocephaly	Generalized flexion contractures			Ciliopathy	AR <i>KIF7</i> at 15q26 <i>GLI3</i> at 7p13
Adducted thumbs (see also clasped thumbs, MASA, Table 161-4 and clasped thumbs Table 161-2	201550	Thumbs flexed Developmental delay Micrognathia, cleft palate Craniosynostosis Microcephaly Dysmyelination Pectus Excavatum Hydrocephaly	Thumbs  Wrists Elbows Knees Feet	Flexion/ adduction Limited extension Adducted Flexion Talipes equinovarus, varus	Do poorly	Chromosomes: normal EMG: abnormal Cine-esophagoscopy: abnormal Lab: proteinuria Pathology: displaced tendons, dysmyelination Degeneration of AHC of spinal cord	AR
Adenylosuccinate lyase deficiency	103050	Microcephaly IUGR Hypotonia Self mutilation MR	Generalized flexion contractures		Progressive early lethal respiratory failure	Pachygyria Cerebral atrophy White matter gliosis Urinary ↑ S-Ado and/or SAIC Ar	AR <i>ADSL</i> at 22q13.1
Aicardi–Goutières syndrome (Cree encephalitis)	225750 606609 606754 610333 610329 610181 610326	Encephalopathy Intracranial calcifications Severe MR Mimics CNS infection	Generalized contractures		Do poorly May lose digits	CNS with multiple vascular scarring and loss of tissue CSF lymphocytes	AR <i>TREX1</i> at 3p2 <i>SAMHD1</i> at 20q11.2 <i>RNASEH2A</i> at 19p13.1 <i>RNASEH2B</i> at 13q14.3 <i>RNASEH2C</i> at 11q13.1
Al-Awadi–Raas– Rothschild syndrome	276820 601570	Upper and lower limb deficiency Hypoplastic pelvis TE fistula Imperforate anus Cleft palate Renal agenesis	Generalized flexion contractures		Lethal	Osteopenia	AR <i>WNT7A</i> at 3p

**TABLE 161-4    Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Le**

Entity	MIM#	Primary Features	Contractures			Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position	Progression		
Antley–Bixler syndrome (also phenocopy maternal fluconazole, two subtypes related to ± steroidogenesis)	124015	Unusual facies with frontal bossing and midface hypoplasia	Fingers	Flexion	DD when O <sub>2</sub> deprived or severe	ECG, EMG, lab: WNL	AR
	176750		Wrists	Flexion at 190, carpal synostosis	May do well	Radiographs: radiohumeral synostoses, tarsal synostoses, choanal atresia, occasional radial ulnar synostosis	<i>POR</i> at 7q11.2
	201750	Bent long bones			cranosynostosis		steroidogen defect
	207410	Craniosynostosis and proptosis	Elbows	Radio-humeral synostosis	May have Arnold–Chiari		<i>FGFR2</i> at 10q
		Contractures – camptodactyly (70%) Radiohumeral synostosis (100%) Scoliosis	Ankles  Toes	Tarsal synostosis, flexed Camptodactyly	Normal intelligence Subtypes related steroidogenesis and genital anomalies		without steroidogen defect Phenocopy with maternal fluconazol
ARC (Neselo of syndrome) (arthrogryposis, renal dysfunction, cholestasis syndrome – two subtypes)	208085	Joint contractures	Hands	“Clubbed”	Lethal	Autopsy: rarefaction of anterior horn cells	AR
	608552	Liver disease (jaundice and biliary stasis)	Feet	Calcaneus and talipes equinus		Pigmentary storage disease in liver cells, nephrocalcinosis	<i>VPS33B</i> at 15q
	613401	Renal dysfunction with nephrocalcinosis				Renal tubular cell degeneration 10% cardiac defect	<i>VIPAR</i> at 14q
Bartsocas–Papas syndrome (lethal popliteal pterygium)	119300	Contractures with marked webs	Flexion of all joints (particularly knee to foot), webs		Flexion, webs	Usually lethal; 1/4 survive to 20 months	AR
	263560	Perioral and perianal and distal limb skin dysplasia Syndactyly leading to mitten hand and foot Cleft lip, nose, and palate Microcephaly IUGR Ankyloblepharon					
Blepharophimosis, joint contractures, MR, Dandy–Walker malformation syndrome		Blepharophimosis Dandy–Walker malformation Auricular pits Cerebellar abnormalities MR	Hips Knees	Flexion Flexion	Nonprogressive	CT: absence of corpus callosum, Dandy–Walker malformation, aplasia of cerebellar vermis	AR

Bohring–Opitz syndrome	605039 612990	Severe MR (100%) Microcephaly Trigonocephaly Prominent eyes IUGR (83%) Palate high or cleft Contractures (60%) Cardiac (50%)	Hands Wrists Elbows Hips Knees Ankles	Clasped Flexed Flexed Extended Extended Extended	Lethal (40% infancy)	R/O Opitz C-BOS mutation R/O trisomy 3p	AR <i>ASXL1</i> at 20q
Bowen–Conradi syndrome	211180 611531	IUGR Microcephaly Micrognathia Prominent nose Cloudy corneas Large ears Clinodactyly and rockerbottom feet	Hands Hips Feet	Ulnar deviation Dislocated Valgus	Lethal	Absent vermis, hypoplastic cerebellum	AR <i>EMG1</i> at 12p1
Campomelic dysplasia	114290 608160	Curvature and shortening of long bones, particularly femur and tibia  Pretibial dimpling over curves Cleft palate, flat face Hypoplasia of facial bones, scapulae, and fibulae ± Ambiguous genitalia ± Craniosynostosis XY may have genital defects	Elbows Hips Feet	Synostosis CDH Calcaneovalgus or equinovarus	Lethal, perinatal or death in infancy observed  2/3 males present as females	Radiographs: bowing of long bones, fractures, platyspondylia, abnormal enchondral ossification, cervical vertebral anomalies Pathology: ambiguous genitalia Chromosomes: normal or may have translocation involving 17q	AR <i>SOX9</i> gene mutations 17q23  Some cases of mutations campomelic
Carbohydrate-deficient glycoprotein syndrome (includes congenital disorders of glycosylation)	212065 601785	Ataxia Hypotonia MR Severe neonatal onset Hydrops Retinitis pigmentosa, esotropia Peculiar subcutaneous fat Nipple retraction Hypogonadism	Elbows Knees	Flexion Flexion	Often lethal Axial hypotonia Bleeding tendency Peripheral neuropathy Severe MR Liver disease Ascites	Lab: low cholesterol, high triglycerides, transferin low CT scan: cerebellar atrophy, demyelination Autopsy: liver with fatty changes and cirrhosis Renal cysts Cerebellar hypoplasia Cardiomyopathy	AR <i>PMM2</i> gene mutations 16p13.3 <i>PM1</i> gene m at 15q22.3
Central core disease– congenital onset (see also congenital myopathies)	117000 180901	Contractures Hypotonia Kyphoscoliosis Fetal akinesia	Generalized flexion contractures  Hips	Dislocated	Maybe lethal May be at risk for malignant hyperthermia	Muscle shows characteristic eccentric cores	AR (includes minicore d AD (sarcomer disorganiz <i>RYR1</i> gene mu at 19q13.1

TABLE 161-4

Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Let

Entity	MIM#	Primary Features	Contractures			Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position	Progression		
Cerebro-oculo-facio-skeletal (COFS) syndrome (Pena-Shokeir II) Types 1-4	126340	Microcephaly, IUGR	Fingers	Flexion, medially deviated	FTT, lethal	Dysmyelination, cerebral atrophy	AR
	126380	Cataracts, microphthalmia,			Progressive	Chromosomes: normal	<i>ERCC6 (CSB)</i> at 10q11.23
	133530	deep-set eyes, retinal	Elbows	Flexion	degeneration	Radiographs:	<i>ERCC2</i> at 19q
	214150	pigmentary changes	Hips	Flexion	Brain atrophy	platyspondylia,	<i>ERCC5</i> at 13q
	278780	Micrognathia	Knees	Flexion	Severe DD	membranous cranial bones, decreased ossification,	<i>ERCC1</i> at 19q
	609413	Abnormal large ears	Feet	Calcaneovalgus, rockerbottom		osteoporosis; renal anomalies, osteopetrosis can be seen	
	610756	Overlapping flexed fingers					
	610758	Prominent nasal root Kyphoscoliosis Hypotonia					
Chondrodysplasia punctata (rhizomelic dysplasia, R/O maternal warfarin)	215100 601757	Symmetrical rhizomelic shortening of limbs Stippled epiphyses particularly centrally Characteristic facial features, flat face Microcephaly Cataracts CHD Severe MR Mottled irregular skin	Generalized flexion contractures Feet	Talipes equinovarus	Lethal or severe MR	Peroxisomal disorder Radiographs: punctuate calcifications, flared metaphyses with epiphyseal stippling, vertebral clefing	AR <i>PEX7</i> gene mutation at 6q22-q
Clasped thumbs and MR syndrome (also see adducted thumbs and MASA syndrome, Table 161-4)	303350	Adducted thumb ± camptodactyly ± Moderate to severe MR Microcephaly to hydrocephaly ± aqueductal stenosis	Hands Feet	Camptodactyly Camptodactyly and clubfoot	Lethal to long life	Malmigration of neurons, hypoplastic thumb	X-linked recessive Related to X-linked hydrocephalus
Congenital disorders of glycosylation (see carbohydrate-deficient glycoproteins syndrome)							
Contractural	121050	Arachnodactyly	Fingers	Flexion	Often lethal	Autopsy: absence of subcutaneous fat	AD
arachnodactyly (severe congenital)	612570	Camptodactyly Crumpled ear Microphthalmia Micrognathia	Elbows Spine Knees	Flexion Scoliosis Flexion			<i>FBN2</i> mutation 5q23-q31

Crisponi syndrome (cold-induced sweating syndrome; Sohar Crisponi syndrome)	601378 604237	Paradoxical contractures Hyperthermia Hypersalivation Cold-induced sweating Feeding difficulties Camptodactyly Pinched face Trismus	Generalized flexion contractures		Usually death in first few years Feeding difficulty Respiratory Scoliosis progresses	Normal muscle biopsy CT, MRI: brain within normal limits	AR Mutation in C at 19p13.1
Dandy–Walker, mental retardation, basal ganglia disease and seizures (Pettigrew syndrome) see also Ohdo syndrome and blepharophimosis AR syndrome	304340	Hypotonia Spasticity Contractures Seizures Choreoathetosis Coarse facial features	Elbows Knees Feet	Flexion Flexion Talipes equinovarus	Severe MR and seizures	Cystic enlargement of fourth ventricle Cerebral atrophy Cerebellar hypoplasia Dandy–Walker Iron in basal ganglia	X-linked Xq25–q27
Dyggve–Melchior–Clausen dysplasia	223800 607461	Camptodactyly Short trunk MR Short long bones Short neck	Fingers Hips	Stiff, claw-like Dislocated	Progressive Spinal cord compression at C1	Radiographs: platyspondylia, irregular lacy iliac crest, odontoid hypoplasia, vertebral notches ER changes in biopsy Urine shows MPS	AR <i>DYM</i> gene mu at 18q12–
Dyssegmental dysplasia (Rolland–Desbuquois)	224400	Short trunk Thick, broad long bones Cleft palate Stiff joints Variable size vertebrae Limitation of full extension throughout	Vertebrae  Generalized flexion contractures	Segmental dysplasia	Lethal	Segmental spinal defects	AR Two subtypes
Encephalopathy, edema, hypsarrhythmia, optic atrophy syndrome (PEHO syndrome)	260565	Progressive encephalopathy Edema Hypsarrhythmia Optic atrophy Severe hypotonia/hyperreflexia Characteristic facial features with pear-shaped face	Fingers  Feet	Camptodactyly, tapering Talipes equinovarus	Lethal by age 6 yrs Profound MR	Autopsy: small cerebellum, spongy vacuolation in cerebral cortex, loss of Purkinje cells and granule cells with proliferation of Bergmann glia	AR
Eagle–Barrett syndrome (prune-belly syndrome)		Renal anomaly Prune belly Pulmonary hypoplasia Potter facies Imperforate anus	Multiple flexion contractures, particularly lower limb		Often lethal	Various GU and GI anomalies Arthrogryposis common	Usually sporadic

TABLE 161-4     **Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Let**

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
FG syndrome (Opitz–Kaveggia; also see Lujans Fryns syndrome)	300188 305450	MR Large head, broad tall forehead with cowlick Hypotonia ± joint contractures Imperforate anus and other GI abnormalities, including constipation ± CHD Seizures; CNS anomalies ± Contractures Hyperactive	Fingers Knees Wrists Ankles  Feet	Ulnar deviation Radial deviation Limited extension Lateral displacement Contractures	Nonprogressive	Chromosomes: normal Pathology: CNS abnormal, partial agenesis of corpus callosum Radiographs: ± agenesis of corpus callosum	X-linked recessive <i>FGS1</i> at Xq13 <i>MED12</i> <i>FLNA</i> at Xq28
Fowler-type hydranencephaly	225790 610865	Proliferative vasculopathy Hydrocephalus Hydranencephaly Fetal akinesia	Generalized flexion contractures		Lethal Prenatally diagnosable	Proliferative vasculopathy Glomerular vasculopathy Diffuse ischemic lesions in CNS with calcifications	AR <i>FLVCR2</i> at 14q24.3
Fryns syndrome	229850	Coarse face, cloudy corneas Cleft palate, micrognathia Hypoplasia/aplasia of lungs Digitalization of thumbs Distal limb deformities and hypoplasia GU anomalies ± absent diaphragm Omphalocele	Fingers  Thumbs	Flexion of PIP joints Digitalization	Lethal	Chromosomes: normal, occasional translocation Radiographs: hands and feet – rudimentary digit development Pathology: hypoplasia of lungs and diaphragm, broad clavicles, CNS abnormality, hydro- cephalus CGH normal	AR
Fukutin mutations includes (cerebro-oculo muscle syndrome, HARD ± E, muscle eye brain (MEB), Walker– Warburg syndrome)	236670 253280 253800 606596 606612 607155 607423 607439 607440 613153 613154 613150	Muscular dystrophy Cerebral atrophy/ heterotopia/myelin abnormalities Lissencephaly/ polymicrogyria Optic atrophy MR	Generalized flexion contractures		Lethal Progressive	CT: cerebral atrophy, dilated cerebral ventricles, cerebral cysts, lissencephaly, and polymicrogyria EEG: abnormal Lab: elevated CPK Muscle biopsy: dystrophic changes	AR <i>FKRP</i> at 19p11 <i>FCMD</i> at 9q31 <i>POMT1</i> at 9q31 <i>POMT2</i> at 14q24 <i>FKTN</i> at 9q31 <i>POMGNT1</i> at 10p15 <i>LARGE</i> at 22q13

Gaucher disease, perinatal lethal	606463 608013	Hydrops Hepatosplenomegaly Ichthyosis Facial storage	Generalized flexion contractures		Progressive lethal	Glucocerebrosidase deficiency	AR <i>GBA</i> at 1q21
Gelophysic dysplasia	231050 612277	Short stature and short bones Campto- and brachydactyly Aortic stenosis Happy facial appearance MR	Fingers Feet Hips	Camptodactyly Talipes equinovarus Dislocated	Progressive	Radiographs: dysostosis multiplex, inclusions in muscle cells	AR <i>ADAMTSL2</i> at 9q34.2 <i>FBN1</i> at 15q2
Genitopatellar syndrome	606170	Severe MR Microcephaly Absent corpus callosum Absent patella Genital anomalies	Dislocations and flexion contractures		Poor outcome	CNS anomalies	AR <i>KAT6B</i> at 10q
German syndrome	231080	Generalized contractures Edema Fetal akinesia sequence Hypotonia Hypotonic facies Cleft or high palate Large ears MR	Generalized flexion contractures		Nonprogressive Edema improves	Muscle shows microscopic glycogen, brain apparently normal	AR
Hypomyelination (see myopathies)							
Ives microcephaly, micromelia syndrome	251230	IUGR Microcephaly Fused elbows Short forearm ± 1 bone Hypoplastic hand missing whole digits	Generalized flexion contractures		Lethal	Pathology: renal dysplasia, decreased myelin	AR
Lenz–Majewski syndrome (hyperostotic dysplasia)	151050	Progressive osteosclerosis or osteopetrosis Synostosis and symphalangism Enamel abnormalities Broad ribs and clavicles Pinched nose, large ears, prominent eyes ± Choanal atresia MR Thin skin with prominent veins Delayed closure of fontanelle	Generalized flexion contractures		Progressive		?AD

TABLE 161-4 Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Let							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Leprechaunism (Donohoe syndrome)	147670 246200	IUGR Specific elfin facies Hirsutism Loose, dry skin Contractures	Hands Feet	Flexion Talipes varus	Lethal Spinal muscular atrophy	Associated with insulin receptor gene Autopsy: renal hyperplasia, focal changes in liver, calcified deposits in kidneys, aberration of endocrine system, brain normal	AR <i>INSR</i> gene mutation at 19p13.2
Lethal arthrogryposis with anterior horn cell disease (Finnish) (LAAHD)	253310 603371 611890	Severe hydrops IUGR Hypoplastic muscle Thin spinal cord Early <i>in utero</i> onset Hypoplastic lungs Anterior horn cell loss	Generalized flexion contractures Occasional extended knee Kyphosis		Lethal	Early onset <i>in utero</i> Autopsy shows loss of anterior horn cells Severe neurogenic changes	AR Allelic to LCCS2 <i>GLE1</i> at 9q34
Lethal congenital contracture syndrome 1 (Finnish)	253310 603371	Generalized contractions Hypoplastic lungs Edema Marked fetal hydrops Mild webbing	Generalized flexion contractures		Lethal	Nonspecific changes of fetal akinesia found at autopsy Pulmonary hypoplasia Decreased AHC with degeneration Thin bones	AR <i>GLE1</i> at 9q34
Lethal congenital contracture syndrome 2 (Israeli Bedouin)	190151 607598	Lethal congenital contractures IUGR No edema Hydramnios Extended bladder	Wrists, elbows, hips, knees, ankles	Flexion contractures	Lethal	Nonspecific	AR <i>ERBB3</i> at 12q
Lethal congenital contracture syndrome 3	611369	Lethal congenital contractures IUGR No edema Hydramnios	Generalized flexion contractures May have extended legs		Lethal	Similar to LCCS2	AR <i>PIP5K1C</i> at 19
Lissencephaly with fetal akinesia sequence (3 types)	257320 600514 601160	Fetal akinesia with lissencephaly Microcephaly Hydrocephaly Hydrops	Flexion contractures		Lethal Pulmonary hypoplasia	Lissencephaly Absence of corpus callosum and vermis Cystic cerebellum Stippled epiphyses	AR, consanguinity Type 1: <i>PAFAH1B1</i> 17p13.3 Type 2: <i>RELN</i> 7q22.1 Type 3: with brain dysplasia

Marden–Walker syndrome (heterogenous with an excess of males)	248700	Hypertelorism, blepharophimosis, ptosis Apparent arachnodactyly Joint contractures Developmental delay Kyphosis, scoliosis Hypotonia Characteristic facies: immobile, depressed nasal bridge	Fingers Generalized flexion contractures Feet	Camptodactyly Equinovarus or rockerbottom		Pathology: atrophic muscles, CDH, microcysts in kidneys, ± muscle fiber size Hematology and urine: normal CT: Dandy–Walker malformation, hypoplastic corpus callosum	AR
Martsolf syndrome (includes Warburg Micro syndrome)	212720 609275	Short stature MR Hypogonadism (small penis) Malocclusion Cataracts, microphthalmia Hypermobility tapering fingers Microcephaly Arnold–Chiari malformation Diplegia	Adducted thumbs Clubfeet	Flexion contractures	Nonprogressive	Cerebral atrophy Dilated ventricles	AR <i>RAB3GAP2</i> mutations 1q41 <i>RAB3GAP1</i> at <i>RAB18</i> at 10p
MASA syndrome (see also adducted thumbs, clasped thumbs, Table 161-4)	303350 308840 600118 602536	Adducted thumbs Aphasia Shuffling gait Short stature MR Spastic paraplegia	Generalized flexion contractures		Nonprogressive	CNS apparently normal	X-linked <i>LICAM</i> at Xq2
Megalocornea and skeletal anomalies		Megalocornea Usual-shaped hand Prominent forehead, saddle nose, large ears, micrognathia Gibbus/kyphoscoliosis Contractures distally MR IUGR	Fingers Feet	Camptodactyly Talipes equinovarus		Chromosomes: normal Radiographs: kyphoscoliosis, thin cortical bones of skull	AR
Meningomyelocele (see Table 161-3)		Spinal lesion Paralysis ± joint contractures ± Others	Usually lower limbs, depending on lesion position Flexion	Clubfeet	Can be lethal	X-rays show bony defect often associated with CNS problems	Multifactorial

Myelinopathies with multiple congenital contractures	129010 145900 159440 601097 605725	Hypotonia Decreased facial movement Ophthalmoplegia Decreased muscle mass PDA Feeding problems Scoliosis	Generalized flexion contractures		Nonprogressive Pulmonary problems Early death	Markedly decreased myelin and white matter	AR Mutations may include <i>ERG2</i> at 10q23.3 <i>MPZ</i> at 1q23.3 <i>PMP22</i> at 17p11.2 <i>PRX</i> at 19q13.32
Myhre contractures with muscular hypertrophy syndrome		Distal contractures Muscle hypertrophy Hearing loss Short stature MR CHD	Generalized flexion contractures			Radiographs: thickened calvaria, broad prominent mandible, broad ribs, flattened vertebrae	AD
Myopathies with multiple congenital contractures (see also nemaline myopathy and central core disease)	102610 161650 161800 180901 255310 256030 600016 603590 608441 612540	Hypotonia, weakness Decreased facial movement $\pm$ Ophthalmoplegia Decreased muscle mass PDA Feeding problems Scoliosis IUGR Pulmonary hypoplasia	Generalized flexion contractures		Nonprogressive Pulmonary problems, respiratory failure	CNS variable anomalies May have muscle biopsies with intranuclear rods, central core rods, nemaline rods Markedly decreased myelin and white matter	Mutations may include: <i>BIN1</i> at 2q14.3 <i>CNTN1</i> at 12q24.31 <i>SYNE-1</i> at 6q25.1–q25.3 <i>LARGE</i> at 22q13.31 <i>ACTA1</i> at 1q42.1 <i>RYR1</i> at 19q13.32 <i>NEB</i> at 2q23.32
Myotonic dystrophy, severe congenital	160900	Mother with myotonic dystrophy Poor suck, difficulty swallowing Generalized hypotonia Facial diplegia Cataracts Ptosis MR Polyhydramnios	Generalized flexion contractures		Progressive, limited life expectancy Prenatally diagnosable clinically and molecularly	Biopsy: muscular dystrophy Pathology: abnormal CNS, mitral valve prolapse EMG may be positive	AD with anticipation Triple repeat expansion greater expansion when transmitted from mother <i>PMPK</i> at 19q13.32
Neu–Laxova syndrome	256520	Lissencephaly Microcephaly Absence of corpus callosum Short neck Hypertelorism Micrognathia Exophthalmos Syndactyly Edema IUGR Open eyes Ichthyotic skin changes	Fingers Wrists Elbows Hips Knees Feet	Overlapping Flexion Flexion Flexion Rockerbottom	Lethal Prenatally diagnosable	Chromosomes: normal Pathology: lissencephaly, absent corpus callosum, cerebellar hypoplasia, small placenta, short umbilical cord, skin with ichthyotic changes	AR

Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Neuromuscular disease of the larynx		IUGR Abnormal CNS Pierre–Robin facies Respiratory distress, absent arytenoid cartilage No visceral malformations	Hands 3rd finger Feet	“Clubbed” Flexion Talipes equinovarus	Lethal	Autopsy: absent arytenoid cartilage, brain abnormal, neuromyopathic changes in limb and laryngeal intrinsic muscles  Normal chromosomes	Sporadic AD 5q31
Osteogenesis imperfecta, congenital lethal, “crumpled bone type” (type II)	120160	Short limbs	Wrists	Flexion	Lethal, often stillborn	Radiographs: wormian bones, fractures, cystic changes – long bones, flattened vertebrae, poor mineralization, crumpled bones Type 1 collagen defect	AD <i>COL1A2</i> at 7q <i>COL1A1</i> at 17q <i>FKBP10</i> at 17q
	120150	fractures – poor	Elbows	Flexion			
	166210	mineralization, wormian bones	Knees	Webbing			
	610698	Blue sclera, shallow orbits, small nose ± Contractures, hydrocephalus	Feet	Fixed			
Otopalatodigital syndrome, type II	300017	Deafness, conductive	Fingers	Broad distal phalanges		Radiographs: facial bones hypoplastic; secondary ossification center at base of metacarpals, broad distal phalanges, pectus excavatum	X-linked recessive <i>FLNA</i> at Xq28
	304120	Dwarfism/bone dysplasia					
		Adontia, soft cleft palate	Wrists	Limited supination			
		Characteristic facies: hypertelorism, frontal bossing Mild MR Broad distal phalanges	Elbows Toes	Limited extension Clinodactyly, broad distal phalanges			
Pena–Shokeir phenotype (ankylosis, facial anomalies, and pulmonary hypoplasia) (type 1)	208150	IUGR CNS abnormalities Ankylosis of joints Pulmonary hypoplasia Polyhydramnios, small placenta, short umbilical cord Hypertelorism, micrognathia Fetal akinesia sequence	Hands Elbows Hips Knees Feet	Camptodactyly Flexion Ankylosis Flexion Rockerbottom	Lethal in almost all cases Prenatally diagnosable	Autopsy: congenital myopathy, abnormalities of cerebral cortex and cerebellum Pathology: lung hypoplasia Chromosomes: normal	Some sporadic AR Many subtypes with familial recurrence reported At least 18 different familial forms on basis of changes

Phosphofructokinase deficiency, infantile (glycogen storage VII)	232800 610681	Myopathy High-arched palate Microretrognathia Developmental delay Seizures Corneal clouding	Hands Wrist Hips Knees Feet	Flexion Camptodactyly Flexion Flexion Talipes equinovarus	Progressive respiratory failure Treat with ketogenic diet Most die without treatment	EMG: low amplitude Lab: CPK normal, aldolase elevated, PFK absent, myophosphorylase normal Muscle biopsy: variation in fiber size, subsarcolemmal vacuoles, excess glycogen accumulation	AR <i>PFKM</i> at 12q13
Potter syndrome	164761 191830 611559	Renal agenesis Flattened face Large floppy ears Micrognathia Skin crease under eyes Wrinkled sin Joint contractures Oligohydramnios Lung hypoplasia Broad hands, clubfeet	Hands Wrists Elbows Feet	"Spade-like" Flexion Flexion Talipes equinovarus	Lethal	Chromosomes: normal Autopsy: ± absent uterus and vagina, pulmonary hypoplasia, kidneys and ureters absent or rudimentary, fetal akinesia sequence	Sporadic, occasional AR/AD <i>RET</i> at 11q11.2 <i>UPK3A</i> at 22q11.2
Prader-Willi habitus, osteoporosis, hand contractures syndrome (Urban, Rogers, Meyer)	264010	MR Short stature Obesity Genital abnormalities Hand and foot contractures	Hands Feet	Flexion Fixed		Radiographs: wormian bones, osteoporosis Thyroid: normal	AR
Restrictive dermopathy	150330 275210 606480	Flexion contractures Tight, thin skin Open eyes and mouth Microcephaly ± CNS anomalies	Hands Elbows Hips Knees Ankles	Flexion Flexion Flexion Flexion Flexion	Lethal Prenatally diagnosable	Skin histology: hyperkeratotic stratum corneum with hyperkeratotic keratinization, hypoplastic sebaceous structures and eccrine sweat glands, absence of dermal ridges and thin dermis May have CNS abnormalities, particularly posterior columns	AR <i>DOK7</i> at 4p16.3 <i>RAPSN</i> at 11p15.5

TABLE 161-4 Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Learning Disability							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Ritscher–Schinzel syndrome (cranio–cerebro–cardiac, 3C syndrome)		Prominent forehead Ocular coloboma Cleft palate Cerebellar vermis hypoplasia Dandy–Walker Hydrocephaly Cardiac – multiple structural defects Deafness Scoliosis	Hands Generalized flexion contractures	Camptodactyly	D/D Multiple organ anomalies	Vertebral anomalies Renal anomalies	AR
Roberts syndrome (pseudothalidomide syndrome, SC syndrome)	268300 609353	Microbrachycephalia, ± craniosynostosis	Elbows	Radiohumeral synostosis	Usually lethal	Chromosomes: can have “puffing” phenomenon Pathology: CHD, renal anomalies	AR <i>ESCO2</i> at 8p21
		Limb reduction ±	Knees	Femorotibial fusion			
		Humeroradial synostosis ± Cleft lip and palate Characteristic facies Moderate to severe MR ± IUGR	Feet	Talipes calcaneovalgus			
Schinzel–Giedion syndrome	269150 611060	Hypertrichosis CHD	Fingers Feet	Camptodactyly Talipes equinovarus	Usually lethal	CNS: small brain, hypoplasia of corpus callosum Fatty liver Neuroectodermal sacrococcygeal tumor	AR <i>SETBP1</i> at 8p11
		High, prominent forehead Hydronephrosis MR Camptodactyly Split sternum Choanal atresia Abundant skin	Generalized flexion contractures				
Smith–Lemli–Opitz syndrome – severe	270400 602858	Camptodactyly and syndactyly ± polydactyly CNS structural anomalies Renal agenesis/cysts/dysplasia Pulmonary segmentation Hypotonia	Generalized flexion contractures		Lethal when severe	Multiple internal anomalies of all systems Abnormal cholesterol metabolism	AR <i>DHCR7</i> at 11q13
Sotos-like syndrome		Large size	Elbows	Flexion	Awkward Peculiar speech	Neonatal jaundice NSD1 neg	AR
		Large head	Wrists	Flexion			
		MR	Hips	Flexion			
		Kyphoscoliosis	Knees	Flexion			
		Edema	Ankles	Flexion			

Presented by: <https://jafrillany.org>

Spastic paraplegia (Goldblatt syndrome)	184260	Spastic paraplegia MR Optic atrophy Mild ataxia	Feet	Talipes equinovarus	Progressive		X-linked recessive Mapped to Xq21–Xq22
Spinal muscular atrophy (SMA1, see also chromosome 5q deletion)	253300 600354	Hypotonia Respiratory insufficiency	Generalized flexion contractures		Progressive Lethal		AR <i>SMN</i> at 5q13 Usually all four alleles abnormal or absent
Spondylospinal–thoracic dysostosis	601809	Short spine with defects Fusion of and missing vertebrae Pterygia ± Cleft palate Crablike thorax	Fingers Wrists Elbows Hips Knees Feet	Camptodactyly Flexion Flexion Flexion Flexion Contractures	Usually lethal Pulmonary failure	Radiographs: vertebral anomalies	AR
Trigonocephaly (C) syndrome	211750	Trigonocephaly (triangular shape) Metopic suture fusion Nose with broad root Anteverted nares Hypotelorism MR	Fingers  Elbows Hips Knees Feet	Campto- and clinodactyly  Flexed Dislocated Flexed Clubbed	Often lethal	Chromosomes: normal EEG: abnormal	AR <i>CD96</i> at 3q13.13–c
Weaver syndrome	277590 606681	Macrosomia Accelerated skeletal maturation Camptodactyly Unusual facies	Fingers Feet	Camptodactyly Talipes equinovarus		Radiographs: broad distal femora and ulnae	Sporadic <i>NSD</i> mutations 5q35
Wieacker muscular atrophy and contractures	314580	Clubfeet Progressive distal atrophy Dyspraxia of eye and tongue muscles Mild MR	Feet	Talipes equinovarus	Progressive		X-linked recessive
X-linked arthrogryposis type 1, anterior horn cell loss	301830 314370	Severe contractures Hypertelorism Camptodactyly Hypoplastic and thin nails Small jaw Seizures Severe kyphoscoliosis	Hands Elbows Hips Knees Ankles	Camptodactyly Flexion Flexion Flexion Flexion	Decreased movement <i>in</i> <i>utero</i> Lethal by 2 yrs Often breech	Autopsy: anterior horn cell disease, infantile spinal muscular atrophy EMG: neurogenic	X-linked <i>UBE1</i> at Xp11.23
X-linked arthrogryposis type 2		Clasped thumbs Wide alveolar ridges Bilateral ptosis “Saddle bag” scrotum Small penis	Knees	Extension	Severe but not lethal	Muscle biopsy: abnormal muscle fibers	X-linked

TABLE 161-4     Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation and/or Lethality

Entity	MIM#	Primary Features	Contractures			Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position	Progression		
X-linked arthrogryposis type 5	300158	Profound MR Microcephaly, asymmetrical facies Hypogonadism Joint hypermobility, excess fingertip arches, long palms Esotropia Scoliosis	Fingers Feet Toes	Camptodactyly Rockerbottom Camptodactyly, hallux valgus	Delayed bone growth Short	Fragile X negative Radiographs: thick calvaria, bifid sternum	X-linked Mapped to Xq23–q27
Zellweger syndrome (cerebro–hepato–renal syndrome)	214100	CNS impairment, IUGR Hypotonia ± joint contractures Myopathic facies Hepatomegaly High forehead with delayed closure of sutures	Generalized flexion contractures		Lethal	Chromosomes: normal Radiographs: calcification density over ischium and hip joints, stippling of patella and hands, agenesis of corpus callosum Pathology: lissencephaly, polymicrogyria, renal cysts, abnormal liver function with iron deposits, peroxisomal disorder ECG, EEG: abnormal	AR Peroxisomal abnormalities <i>PEX1</i> gene mu- tations at 7q21–q <i>PEX2</i> gene mu- tations at 8q21.1 <i>PEX3</i> gene mu- tations at 6q21.1 <i>PEX5</i> gene mu- tations at 12p13.3 <i>PEX6</i> gene mu- tations at 6p21 <i>PEX12</i> gene mutations <i>PEX14</i> gene mutations at 1p36.2 <i>PEX26</i> gene mutations at 22q11.21 Chromosome abnormalities

AR = autosomal recessive; AD = autosomal dominant; CDH = congenital deformity of the hip; CHD congenital heart defect; CNS = central nervous system; CPK = creatine phosphokinase; CT = computed tomography; ECG = electrocardiography; EEG = electroencephalography; EMG = electromyography; ER = endoplasmic reticulum; FTT = failure to thrive; GI = gastrointestinal; GU = genitourinary; IUGR = intrauterine growth retardation; LCCS1/2 = lethal congenital contracture syndrome 1/2; MPS = mucopolysaccharidosis; MR = mental retardation; MRI = magnetic resonance imaging; PDA = patent ductus arteriosus; PIP = proximal interphalangeal; TE = tracheoesophageal; WNL = within normal limits.

TABLE 161-6 Multiple Congenital Contractures Related to Maternal Environment							
Entity	MIM#	Primary Features	Contractures		Progression	Lab Tests, Radiographs, Autopsy Findings	Inheritance
			Body Area	Position			
Attempted termination of pregnancy and/or trauma		Multiple congenital contractures Vascular accidents with secondary loss of tissue	Generalized or localized Mostly flexion		Many involved CNS destruction May be hypotonic	Imaging of brain may show areas of loss Muscle biopsy may show fiber disproportion and fatty replacement	Environmental
Maternal acidosis		Growth restriction Developmental delay Hydrocephaly Axial skeletal malformations	Generalized flexion contractures		Progressive Prenatally diagnosable		Maternal effect
Maternal alcohol consumption – fetal alcohol syndrome		Microcephaly, IUGR Characteristic facial features Joint contractures, palmar creases (73%) ± CHD (50%) MR and behavioral problems	Generalized flexion contractures		Nonprogressive	Pathology: CNS abnormal, CHD	Teratogenic effect of alcohol on fetus
Maternal antibodies against fetal neurotransmitter receptor subunits (see multiple pterygium, Escobar type, Table 161-3; multiple pterygium, lethal; myasthenia gravis, maternal and congenital)		Hypotonia Polyhydramnios	Generalized flexion contractures		Usually stillborn Steroid therapy and plasmapheresis may help Increasing severity with parity	Fetal ACh receptor radioimmunoassay for antibodies	Autoantibodies
Maternal diabetes		Multiple congenital anomalies Sacral agenesis	Any type of combination of multiple congenital contractures		Hypoglycemia early Metabolic disturbance	Maternal glucose control	DMPK gene mutation 19q13.2– Maternal poor control of diabetes

Maternal fluconazole		Bony fusions Radiohumeral synostosis Craniosynostosis	Generalized flexion contractures	May have CNS structural anomalies	Maternal history of consumption	
Maternal hyperthermia		History of maternal fever > 39 °C for several hours Microcephaly ± Microphthalmia ± Cleft palate MR ± Seizures	Generalized flexion contractures	Nonprogressive but may have cerebral palsy	CNS structural anomalies EEG: abnormal	Environmental
Maternal misoprostol ingestion or vaginal suppositories		Terminal limb defects Constriction rings Möbius syndrome CNS abnormalities Hypoplastic muscle Anterior horn cell deficiency Microcephaly	Generalized flexion contractures or amyoplasia-like	Nonprogressive, but often CP and MR	CNS anomalies, including hydrocephaly	Environmental
Maternal multiple sclerosis		Multiple congenital contractures	Generalized flexion contractures	Nonprogressive	Maternal testing	Maternal effects
Maternal muscle relaxant		Fetal akinesia signs	Generalized flexion contractures			History of ingestion during pregnancy
Maternal myasthenia gravis (see also congenital myasthenia gravis and AR myasthenia gravis, Table 161-4)	254200 254300	Pulmonary hypoplasia Kyphoscoliosis Micrognathia Hypotonia	Generalized flexion contractures	May be lethal but may markedly improve with tensilon therapy	May have low ACh receptor antibodies	About 12% of infants born to affected mothers are affected themselves <i>DOK-7</i> at 4p
Prenatal diagnosis by early amniocentesis or CVS		Early CVS or amniocentesis	Lower limb contractures	Nonprogressive	Responds well to PT	

ACh = acetylcholine; AD = autosomal dominant; AR = autosomal recessive; ATP = adenosine triphosphate; CHD congenital heart defect; CNS = central nervous system; EEG = electroencephalogram; ER = enteric reduction; Hb = hemoglobin; IUGR = intrauterine growth retardation; MR = mental retardation.

**TABLE 161-7 Chromosomal Localization of Genes for Disorders with Multiple Congenital Contractures**

Disorder	Chromosomal Localization
<b>Primarily Limb Involvement</b>	
Absence of finger prints	4q22.3 ( <i>SMARCA1</i> )
Bruck syndrome	17p12 ( <i>TLH</i> ) ( <i>PLOD2</i> ), 17q21.2 ( <i>FKBP10</i> ) and 3q23–24 linkage
Clasped thumbs	1q25–q31 ( <i>PRG4</i> )
Continuous contractures	12p13.3 ( <i>KCNA1</i> )
Distal arthrogryposis type 1 and 2B	9p11.3 ( <i>TPM2</i> ), 11p15.5 ( <i>TNN12</i> ), 11p15.5 ( <i>TNNT3</i> ) 17p13MYH3 12q23.2 ( <i>MYBPC1</i> )
Lower limb DA – Fleury type	12q23–24 ( <i>TRPV4</i> )
Mesomelic dysplasia	Xq24–32
Patella aplasia-hypoplasia	17q21–22 ( <i>PTLAH</i> )
Symphalangism/synostosis, coalitions	17q21–22 ( <i>NOG</i> ), 20q ( <i>GDF5</i> )
X-linked arthrogryposis, lower limbs only	2q24–q23
<b>Musculoskeletal Involvement Plus Other System Anomalies</b>	
Camptodactyly–arthropathy–coxa vara–pericarditis syndrome (ARC)	1q24–q25 ( <i>PRG4</i> )
Congenital fiber disproportion	1q42–13 ( <i>ACTA1</i> )
Conradi–Hunermann	(Xp11.23) ( <i>EBP</i> )
Contracture arachnodactyly	5q23–31 ( <i>FBN2</i> ) 12q13
Craniosynostosis syndrome	4p16.3 ( <i>FGFR3</i> ), 8p11.23 ( <i>FGFR1</i> )
Deafness, camptodactyly (DA 6)	11q25 ( <i>CATSAL</i> , <i>CATSHL</i> )
Diastrophic dysplasia	5q32 ( <i>SLC26A2</i> )
Digital arthrogryposis I	9q21.2 ( <i>TNNT3</i> ), 11p15.5 ( <i>TNN12</i> , <i>TNNT3</i> ), and 17p13 ( <i>MYH3</i> )
Distal arthrogryposis type 2B (Sheldon–Hall)	9q21.2 ( <i>TNNT3</i> ), 11p15.5 ( <i>TNN12</i> , <i>TNNT3</i> ), and 17p13 ( <i>MYH3</i> )
Dundar–Sonoda syndrome TARP	15q15.1 ( <i>CHST14</i> )
Ehlers–Danlos IV	2q32.2 ( <i>COL3A1</i> )
Ehlers–Danlos VIII	12p13
Ehlers–Danlos VIB-2	15q15 ( <i>CHST14</i> )
Epidermolysis bullosa dystrophica	3p21.31 ( <i>COL7A1</i> )
Freeman–Sheldon syndrome (DA 2A)	17p13 ( <i>MYH3</i> )
Genitopatallar syndrome	10q22.1 ( <i>KAT6B</i> )
Gordon syndrome (DA IIA, DA3)	17p13.1 ( <i>MYH3</i> )
Hand–foot–uterus syndrome	7p15.2 ( <i>HOXA13</i> )
Holt–Oram syndrome	12q24.1 ( <i>TBX5</i> )
Inclusion-body myopathy	17p13.1 ( <i>MYH2</i> , <i>MYH3</i> )
Kniest dysplasia	12q13.1 ( <i>COLA21</i> )
King–Denborough syndrome/multiple pterygium and malignant hyperthermia	Genes for malignant hyperthermia in 19q13.1 ( <i>RYR1</i> ) and 17q ( <i>MHS3</i> )
Kuskokwim syndrome	17q21.2 ( <i>FKBP10</i> )
Larsen syndrome	3p14.3 ( <i>FLNB</i> ), 3p21.31 ( <i>COL7A1</i> ), AR 8q12.1 ( <i>IMPAD</i> ), 17q25.3 ( <i>CANT</i> ), 5q32 ( <i>DTDST</i> )
Marfan syndrome (severe neonatal)	15q21.1 ( <i>FBN1</i> ), 3p24.2–p25?
MASP1 (3M, Carnevale)	3q27.3 ( <i>MASP1</i> ), 2p25.3 ( <i>COLEC11</i> )
Metaphyseal dysplasia (Jansen)	3p21.31 ( <i>PTH1R</i> )
Metatrophic dysplasia	12q24.1 ( <i>TRPV4</i> )
Möbius syndrome	13q12.2–q13
Moore–Weaver	11p15 ( <i>TNN12</i> )
Multiple pterygium (Escobar type)	2q31.1 ( <i>CHRNA1</i> ), 2q37.1 ( <i>CHRNA1</i> , <i>CHRNA2</i> )
Multiple synostosis, symphalangism	17q21–22 ( <i>NOG</i> ), 20q11.22 ( <i>GDF5</i> ), 13q11 ( <i>FGF9</i> ), 4p16.3 ( <i>DOK7</i> )
Myelinopathies	1q23.3 ( <i>MPZ</i> ), 10q21.1 ( <i>ERG2</i> ), 17p12 ( <i>PMP22</i> ), 19q13.2 ( <i>PRX</i> )
Myopathies	22q12.3 ( <i>LARGE</i> ), 6q25 ( <i>SYNE1</i> ), many others
Nail–patella syndrome	9q34.1 ( <i>LMX1B</i> )
Nemaline myopathy	2q22 ( <i>NEB</i> ), 1q42.13 ( <i>ACTA1</i> )
Neurofibromatosis	17q11–q12 ( <i>NF1</i> )
Neuropathic Israeli-Arab (autosomal recessive)	5qter
Nevo syndrome	1p36.22 ( <i>PLOD1</i> )
Oculo–dental–digital syndrome	6q22.31 ( <i>GJA1</i> )
Otospondylomegapiphyseal dysplasia	6p21.32 ( <i>COL11A2</i> )
Parastremmatic dwarfism	12q24.1 ( <i>TRPV40</i> )
Pfeiffer cardiocranial syndrome	10q26 ( <i>FGFR2</i> ), 8p11.23 ( <i>FGFR1</i> )
Popliteal pterygium syndrome	1q32–q41 ( <i>IRF6</i> )
Proteus syndrome	14q32.32 ( <i>AKT1</i> )

**TABLE 161-7 Chromosomal Localization of Genes for Disorders with Multiple Congenital Contractures—Cont'd**

Disorder	Chromosomal Localization
Puretic–Murray syndrome (infantile hyalinosis)	4q21 ( <i>ANTXR2</i> )
Rigid spine muscular dystrophy	1q36.11 ( <i>SEPN1</i> )
Robino Syndrome	3p14.3 ( <i>WNT5A</i> )
Sacral agenesis	7q36 ( <i>MNX1</i> , Currarino syndrome)
Schwartz–Jampel syndrome	1p36.1 ( <i>HSPG2</i> )
Sheldon–Hall syndrome (DA2)	9p13.3 ( <i>TPM2</i> ), 17p13.1 ( <i>MYH3</i> )
Spondyloepiphyseal dysplasia congenita	12q13.1 ( <i>COLA21</i> )
Stiff man	5q33.1 ( <i>GLRA1</i> ), 4q32.1 ( <i>GLRAB</i> )
Trismus-pseudocamptodactyly	17p12–p13.1 ( <i>MYH8</i> )
Tuberous sclerosis	9q ( <i>TSC1</i> ), 16q ( <i>TSC2</i> )
Ullrich congenital muscular dystrophy	2q37 ( <i>COL6A3</i> ), 21q22.3 ( <i>COL6A1</i> ), 21q22.3 ( <i>COL6A2</i> )
VATER Association	2q31.1 ( <i>HOXD13</i> )
Van den Ende–Gupta syndrome	22q11.21 ( <i>SCARF2</i> )
Waardenburg–Klein	2q25–q37.12 ( <i>PAX3</i> )
Weill–Marchesani syndrome	19p13.3–13.2 ( <i>ADAMS10</i> )
Winchester syndrome	16q13 ( <i>MMP2</i> )
X-linked moderately severe	Xp11.3–q11.2
<b>Musculoskeletal Involvement Plus Central Nervous System Dysfunction and/or Mental Retardation</b>	
Acrocallosal syndrome	7p13 ( <i>GLI3</i> ), 15q26.1 ( <i>K1F7</i> )
Adenyl succinate lyase deficiency	22q13.1–13.2 ( <i>ADSL</i> )
Aicardi–Goutierres syndrome	3p21 ( <i>TREX1</i> ), 11q13.2 ( <i>RNASEH2C</i> ), 13q14.3 ( <i>RNASEH2B</i> ) 19p13.13 ( <i>RNASEH2A</i> ), 20q11.23 ( <i>SAMHD1</i> )
Al-Awadi syndrome	3p25 ( <i>WNT7A</i> )
Antley–Bixler syndrome	7q11.2 ( <i>POR</i> ), 10q26 ( <i>FGFR2</i> )
ARC (Nezelof syndrome)	15q26.1 ( <i>VPS33B</i> ), 14q24.3 ( <i>VIPAR</i> )
Bartsocas–Papas syndrome	20q11.21 ( <i>ASXL1</i> )
Bohring–Opitz syndrome	21q22.3 ( <i>RIPK4</i> )
Bowen–Conradi syndrome	12p13.3 ( <i>EMG1</i> )
Campomelic dysplasia	17q24.3–q25.1 ( <i>SOX9</i> )
Carbohydrate-deficient glycoprotein syndrome	16p13 ( <i>PMM2</i> ); 15q22–qter ( <i>PM11</i> )
Central core disease	19q13.1 ( <i>RYR1</i> )
Cerebro–oculo–facial–skeletal (COFS) syndrome	19q13.2 ( <i>ERCC1</i> ), 13q33.1 ( <i>ERCC5</i> ), 10q11.23 ( <i>ERCC6</i> ), 19q13.32 ( <i>ERCC2</i> )
Chondrodysplasia punctata (rhizomelic)	6q22–q24 ( <i>PEX7</i> )
Clasped thumb and mental retardation	Associated with X-linked hydrocephaly
Cocoon syndrome	10q24.31 ( <i>CHUK</i> )
Congenital muscular dystrophy (merosin deficient)	6q22–23 ( <i>LAMA2</i> )
Contractural arachnodactyly	5q23–31 ( <i>FBN2</i> )
Crisponi syndrome	19p13.11 ( <i>CRLF1</i> )
Dandy–Walker, MR, basal ganglion seizures	Xq25–27
Dyggve–Melchior–Clausen syndrome	18q12–q21.1 ( <i>DYM</i> )
Episodic ataxia/myokymia syndrome	12p13.32 ( <i>KCNA1</i> )
FG syndrome	Xq13 ( <i>MED12</i> ), Xq28 ( <i>FLNA</i> )
Fowler-type hydranencephaly	14q24.3 ( <i>FLVCR2</i> )
Fukuyama congenital muscular dystrophy	9q31.2 ( <i>FKTN</i> ) 9q34.1 ( <i>POMT1</i> ); 14q24.3 ( <i>POMPT2</i> ), 9q31–33 ( <i>FCMD</i> ), 19q13.2 ( <i>FKRP</i> )
Gaucher disease – perinatal lethal	1q22 ( <i>GBA</i> )
Geleophysic dysplasia	9q342 ( <i>ADAMTSG2</i> ), 15q21.1 ( <i>FBN1</i> )
Glycogen storage IV	9q34 ( <i>GLE1</i> )
Leprechaunism	19p13.2 ( <i>INSR</i> )
Lethal arthrogryposis with AHC disease	9q34.11 ( <i>GLE1</i> )
Lethal congenital contractures syndrome (Finnish) I	9q34.11 ( <i>GLE1</i> )
Lethal congenital contractures syndrome (Finnish) II	12q13 ( <i>ERBB3</i> )
Lethal congenital contractures syndrome (Finnish) III	19p13.3 ( <i>PIP5K1C</i> )
Lissencephaly with FADS	7q22.1 ( <i>RELN</i> ), 17p13.3 ( <i>PAFAH1B1</i> )
Martsof syndrome, Warburg micro syndrome	1q41 ( <i>RAB3GAP2</i> ), 2q21.3 ( <i>RAB3GAP1</i> ), 10p12.2 ( <i>RAB18</i> )
MASA syndrome	Xq28 ( <i>L1CAM</i> )
Miller–Dieker syndrome	17q13.2 ( <i>L1S1</i> )
Multiple pterygium syndrome – lethal	2q31.1 ( <i>CHRNA1</i> ); 2q37.1 ( <i>CHRNA1</i> , <i>CHRNA2</i> )
	22q12.3 ( <i>LARGE</i> )

**TABLE 161-7 Chromosomal Localization of Genes for Disorders with Multiple Congenital Contractures—Cont'd**

Disorder	Chromosomal Localization
Muscular dystrophy, congenital, rigid spine	1p35–36 ( <i>SEPN1</i> )
Myasthenia, congenital	11p11.2–p11.1 ( <i>RAPSN</i> ), 17p12–p11 ( <i>CHRNA1</i> ), 17p13–p12 ( <i>CHRNA2</i> )
Myelinopathies	1q23.3 ( <i>MP2</i> ), 10q21.1 ( <i>ERG2</i> ), 17p12 ( <i>PMP22</i> ), 19q13.2 ( <i>PRX</i> )
Myopathy centronuclear	2q14.2 ( <i>BIN1</i> )
Myotonic dystrophy	19q13.3 ( <i>DMPK</i> )
Myotubular myopathy	Xq28 ( <i>MTM1</i> )
Neuromuscular disease of larynx	5q31
Nevo syndrome	1p36.2 ( <i>PLOD1</i> )
Oculodentodigital syndrome	6q21–23.2 ( <i>GJA1</i> )
Osteogenesis imperfecta	7q21.3 ( <i>COL1A2</i> ), 17q21.23 ( <i>COL1A1</i> )
Otopalatodigital II	Xq28 ( <i>FLNA</i> )
Pfeiffer syndrome	10q26 ( <i>FGFR2</i> ), 8p11.23 ( <i>FGFR1</i> )
Phosphofructokinase deficiency infantile (glycogen storage VII)	12p13.3 ( <i>PFKM</i> )
Potter syndrome	11q11.2 ( <i>RET</i> ), 22q13.31 ( <i>UPK3A</i> )
Raine syndrome	7q22.3 ( <i>FAM20C</i> )
Renal adysplasia	10q11.21 ( <i>RET</i> ), 22q13.31 ( <i>UPK3A</i> )
Restrictive dermopathy	4p16.3 ( <i>DOK7</i> ), 11p11.2 ( <i>RAPSN</i> ), 1p34.2 ( <i>ZMPSTE24</i> ), 1q22 ( <i>LMNA</i> )
Robert syndrome	8p21.1 ( <i>ESCO2</i> )
Schinz–Gideon syndrome	18q12.3 ( <i>SETBP1</i> )
Schwartz–Jampel syndrome	1p36.12 ( <i>HSPG2</i> )
Smith–Lemli–Opitz syndrome	11q12–q13 ( <i>DHCR7</i> )
Spinal muscular atrophy	5q13.2 ( <i>SMN</i> )
Spastic paraplegia (Goldblatt syndrome)	Xq21–q22
Spinal muscular atrophy	5q13.2 ( <i>SMN</i> )
Trigonocephaly (C syndrome)	3q13.3–q13.2 ( <i>CD96</i> )
Waardenburg Shah syndrome	22q13.1 ( <i>SOX10</i> )
Walker–Warburg syndrome	3p22.1 ( <i>GTDC2</i> )
Weaver syndrome	5q35 ( <i>NSD1</i> )
X-linked lethal arthrogryposis 1	Xp11.23 ( <i>UBE1</i> )
Zellweger syndrome	Multiple <i>PEX</i> genes
5q deletions (spinal muscular atrophy)	5q13.3 ( <i>SMN</i> ) microdeletions

DA = distal arthrogryposis; MR = mental retardation.

**TABLE 161-8 Types of Arthrogryposis by Chromosome Location**

Chromosome	Short Arm	Long Arm
1	1p34.2: Restrictive dermopathy ( <i>ZMPSTE24</i> ) 1p36.11: MD, congenital, spinal rigidity ( <i>SEPN1</i> ) 1p36.1: Schwartz–Jampel syndrome ( <i>HSPG2</i> ) 1p36.13: Stiff man/baby syndrome ( <i>SEPN1</i> ) 1p36.22: Nevo syndrome ( <i>PLOD1</i> )	1q21: Gaucher perinatal lethal ( <i>GBA</i> ) 1q22: Restrictive dermopathy ( <i>LMNA</i> ) 1q23.3: Myelinopathy ( <i>MP2</i> ) 1q24–q25: Camptodactyly arthropathy coxa vara pericarditis ( <i>PRG4</i> ) 1q25–q31: Camptodactyly–arthropathy–coxa vara–pericarditis ( <i>CACP</i> ) 1q31: Multiple joint stiffness, AR 1q32.2: Popliteal pterygium syndrome 1q41: Martsolf syndrome ( <i>RAB3GAP</i> ) 1q42.13: Congenital fiber disproportion, Nemaline myopathy ( <i>ACTA1</i> ) 2q14.3: Central core myopathy ( <i>BIN1</i> ) 2q21.3 Martsolf syndrome ( <i>RAB3GAP1</i> )

<p>Patella aplasia–hypoplasia syndrome Prader–Willi-like – wormian bones Pseudodiastrophic dysplasia Radioulnar synostosis Saul–Wilson dysplasia Spondyloepiphyseal dysplasia congenita – flat epiphyses and vertebrae Spondylothoracic dysostoses Symphalangism – many types van den Ende–Gupta syndrome Weill–Marchesani syndrome Winchester syndrome Zellweger syndrome – stippling of epiphyses and patellae, calcifications</p> <p><b>Boney Fusions</b> Antley–Bixler – radiohumeral synostosis, coalitions Coalitions Diastrophic dysplasia Hanhart – fused knee or elbow Humeroradial synostosis Ives microcephaly micromelia syndrome – elbows Lenz–Majewski syndrome Liebenburg syndrome Mesomelic dysplasia Multiple synostosis – multiple fusions Ophthalmomandibulomelic syndrome – fusion TMJ Pfeiffer cardiocranial syndromes – humeroradial synostosis Radioulnar synostosis Roberts syndrome – humeroradial synostoses Symphalangism (many types) Waardenburg–Klein syndrome – carpal fusion</p> <p><b>Bowel Abnormality</b> Aarskog syndrome – Hirschsprung malformation (rare) Aase–Smith syndrome – VSD (rare) Al–Awadi syndrome – TEF, IA Alkuraya syndrome – pyloric stenosis Amyoplasia – gastroschisis, bowel atresia, abdominal wall defects Bowen syndrome – omphalocele, umbilical hernia BRESHECK – Hirschsprung “C” syndrome variant – malrotation Distal (2E Hall) – bowel atresia Eagle–Barrett – 1A FG syndrome – imperforate anus Fryns syndrome – omphalocele Lin Gettig – small bowel atresia, omphalocele, umbilical pigmentation Miller–Dieker syndrome – duodenal atresia Mitochondrial defects – atresias Shalev-type distal arthrogryposis – umbilical hernia VATER association – TEF, EA, BA</p> <p><b>Cardiology</b> Aarskog syndrome – ASD, PS (rare) Aase–Smith syndrome – VSD (rare) Acrocallosal syndrome Alkuraya syndrome Antley–Bixler syndrome – ASD, PDA Bohring–Opitz syndrome Bowen syndrome – ASD</p>	<p>“C” syndrome variant – frequent variety of anomalies, VSD, ASP, PDA Camptodactyly, pericarditis, synovitis–pericarditis Camptodactyly, Tel–Hashomer – congenital heart disease Carbohydrate-deficient protein syndrome – cardiomyopathy Cardiac deficiency and asplenia Cardiomeic syndrome Contractural arachnodactyly – congenital heart anomalies Dundar–Sonoda syndrome – CHD, ASD Ectodermal dysplasia and cardiomyopathy Ehlers–Danlos VIII – aortic and mitral regurgitation FG syndrome Geleophysic dysplasia – aortic stenosis Holt–Oram syndrome – structural defects, particularly septal Larsen syndrome – septal defects Lerman–Sagie – murmur, enlarged interventricular septum, PDA Lin–Gettig – VSD Marfan syndrome, congenital – aortic incompetency Miller–Dieker (lissencephaly II) – PDA Mitochondrial defects Myhre muscle hypertrophy Myopathies – PDA Nemaline myopathy – congenital heart disease Neuropathic Israeli–Arab – congenital heart PHAVER syndrome – VSD, ASD, double outlet, coarctation of aorta, pulmonary atresia Pfeiffer cardiocranial syndrome – congenital heart Ritscher–Schinzel – multiple structural defects Robert syndrome Schinzel–Giedion syndrome Stiff man syndrome – heart failure</p> <p><b>Caudal Appendage</b> Ectodermal dysplasia with caudal appendage Gul syndrome Teebi–Shaltout syndrome 3C Carnevale syndrome</p> <p><b>Central Nervous System Structural Anomaly</b> Aarskog syndrome – polymicrogyria (rare) Aase–Smith I syndrome – Dandy–Walker with secondary hydrocephalus and cerebellar anomalies, agenesis corpus callosum Acrocallosal – agenesis corpus callosum, macrocephaly, cerebral and temporal lobe atrophy Adenylosuccinate lyase deficiency – pachygyria, cerebral atrophy, white matter gliosis Adducted thumbs syndrome – dysmyelination Aicardi–Goutieres – calcification, scarring white matter disruption Attempted termination of pregnancy Basal ganglion syndrome – choreoathetosis Bixler microcephaly Blepharophimosis, mental retardation, Dandy–Walker malformation – cerebellar anomalies, absence of corpus callosum Bohring–Opitz – microcephaly Bowen–Conradi syndrome – agenesis of corpus callosum, microcephaly, hypoplastic cerebellum, absent vermis BRESHECK – micro-hydrocephaly CAD – hydrocephaly, microcephaly Carbohydrate-deficient glycoprotein syndrome – cerebellar hypoplasia, dysmyelination</p>
--	--

**TABLE 161-9 Specific Organ or Area of Involvement in Various Disorders with Arthrogryposis (Congenital Contractures)—Cont'd**

<p>Caudal deficiency and asplenia – agenesis of the corpus callosum, meningocele</p> <p>Clasped thumb syndrome – malmigration, microcephaly, hydrocephaly, aqueductal stenosis</p> <p>Coffin–Siris syndrome</p> <p>COFS – dysmyelination, degenerative brain atrophy</p> <p>Dandy–Walker syndrome – cystic enlargement of 4th ventricle, cerebral atrophy, cerebellar hypoplasia, iron in basal ganglion</p> <p>Dundar–Sonoda syndrome – mild hydrocephalus, tethered cord, absent septum pellucidum</p> <p>Fetal alcohol syndrome</p> <p>FG syndrome – agenesis of the corpus callosum</p> <p>Fowler syndrome – proliferative vasculopathy, hydranencephaly, hydrocephaly, diffuse ischemic lesions with calcifications</p> <p>Fukuyama muscular dystrophy – heterotopias, cerebral atrophy, lissencephaly, polymicrogyria, myelin abnormalities</p> <p>Genitopatellar syndrome – absent corpus callosum</p> <p>Illium syndrome – cystic brain, old scars</p> <p>Ives microcephaly, micromelia syndrome – myelin dysplasia</p> <p>Johnson hyperkeratosis and decreased posterior columns</p> <p>Lethal arthrogryposis with AHC disease (Finnish) – loss AHC, thin spinal cord</p> <p>Lin–Gettig – agenesis of corpus callosum</p> <p>Lenz–Majewski – white matter dysgenesis, hydrocephalus, facial palsy (all rare)</p> <p>Lissencephaly with fetal akinesia – lissencephaly, agenesis of corpus callosum and vermis, cystic cerebellum</p> <p>Marden–Walker – Dandy–Walker malformation, hypoplastic corpus callosum</p> <p>Martsolf syndrome – Arnold–Chiari malformation, microcephaly, cerebral atrophy, dilated ventricles</p> <p>Maternal fever – microcephaly</p> <p>Maternal misoprostol – microcephaly, AHC deficiency, structural CNS abnormality</p> <p>Maternal acidosis – microcephaly, hydrocephaly</p> <p>Meningomyocele – cord disruption, +/- CNS structural anomaly</p> <p>Miller–Dieker syndrome – lissencephaly, microcephaly, large ventricles</p> <p>Mitochondrial defects – cerebellar defects, calcifications of basal ganglia, cerebellar anomalies</p> <p>Möbius syndrome – facial diplegia</p> <p>Multiple pterygium syndrome, lethal type – cerebellar hypoplasia</p> <p>Myelinopathies – markedly decreased myelin, white matter</p> <p>Neurofibromatosis – neurofibromas and CNS structural</p> <p>Neu–Laxova syndrome – lissencephaly, agenesis of the corpus callosum, microcephaly</p> <p>Neuromuscular disease of larynx – CNS changes</p> <p>Osteogenesis imperfecta – hydrocephaly</p> <p>PHAVER syndrome – meningocele</p> <p>PEHO syndrome – small cerebellum, spongy vacuolation of cortex, loss of Purkinje cells</p> <p>Pena–Shokeir phenotype – various</p> <p>Restrictive dermopathy – posterior columns</p> <p>Ritscher–Schinzel – cerebellar vermis hypoplasia, Dandy–Walker anomaly, hydrocephaly</p> <p>Schinzel–Giedion syndrome – hypoplastic corpus callosum</p> <p>Smith–Lemli–Opitz syndrome</p> <p>Tuberous sclerosis – structural anomalies</p> <p>van den Ende–Gupta syndrome – cerebellar hyperplasia</p>	<p>Walker–Warburg syndrome – lissencephaly, dysmyelination</p> <p>X-linked anterior horn cell disease</p> <p>Zellweger syndrome – lissencephaly, polymicrogyria, agenesis corpus callosum</p> <p><b>Chest Deformity</b></p> <p>Aarskog syndrome – pectus excavatum (freq)</p> <p>Adducted thumbs syndrome</p> <p>Camptodactyly, Guadalajara – pectus excavatum</p> <p>Carbohydrate-deficient glycoprotein syndrome – inverted nipples</p> <p>Congenital Marfan syndrome – pectus carinatum, excavatum</p> <p>Contractural arachnodactyly – pectus excavatum, carinatum</p> <p>Dundar–Sonoda syndrome – thin ribs, pectus (oce)</p> <p>Ectodermal dysplasia with cardiomyopathy – chest deformity</p> <p>Ectodermal involvement with caudal appendage – shield chest</p> <p>Fryns syndrome – absent diaphragm</p> <p>Hoepffner syndrome – pectus excavatum</p> <p>King–Denborough syndrome – pectus excavatum</p> <p>Lerman–Sagie – ↑ AP diameter, bell-shaped, wide-spaced nipples</p> <p>Lin–Gettig – pectus, widespread nipples</p> <p>Marfan syndrome, severe congenital – pectus excavatum</p> <p>Moebius – absent muscles</p> <p>Multiple pterygium syndrome, Escobar type – restrictive lung disease</p> <p>Nevo syndrome – pectus</p> <p>Pena–Shokeir phenotype – ↑ AP diameter</p> <p>Schinzel–Giedion – split sternum</p> <p>Schwartz–Jampel syndrome – pectus carinatum</p> <p>Spondylothoracic dysostosis – fusion of ribs</p> <p>van Bentham syndrome</p> <p>van Biervliet syndrome</p> <p>X-linked arthrogryposis type 5 – bifid sternum</p> <p><b>Choanal Atresia</b></p> <p>Antley–Bixler syndrome</p> <p>Lenz–Majewski syndrome</p> <p>Schinzel–Giedion syndrome</p> <p><b>Cleft Lip</b></p> <p>Bartsocas–Papavasiliou and cleft nose</p> <p>Diastrophic dysplasia</p> <p>Distal arthrogryposis (Hall IIC)</p> <p>Ectodermal dysplasia with cleft lip/palate</p> <p>Oral cranial digital syndrome – cleft lip and palate</p> <p><b>Cleft Palate</b></p> <p>Aase–Smith syndrome – hard palate, also soft with bifid uvula</p> <p>Adducted thumbs syndrome</p> <p>Bartsocas–Papavasiliou syndrome – cleft nose, lip palate</p> <p>Bixler microcephaly</p> <p>BRESHECK – submucous</p> <p>Bohring–Opitz – cleft, high arched</p> <p>Campomelic dysplasia</p> <p>Diastrophic dysplasia</p> <p>Distal arthrogryposis (2C Hall)</p> <p>Dyssegmental dysplasia</p> <p>Ectodermal dysplasia and cleft lip/palate</p> <p>Focal femoral dysplasia and long philtrum</p> <p>Fryns syndrome</p> <p>German syndrome</p> <p>Gordon syndrome – 40%, familial variability</p> <p>King–Denborough syndrome</p> <p>Kniest syndrome</p> <p>Larsen syndrome</p>

---	---

**TABLE 161-9 Specific Organ or Area of Involvement in Various Disorders with Arthrogryposis (Congenital Contractures)—Cont'd**

<p>Diastrophic dysplasia – calcified cartilage</p> <p>Dundar–Sonoda syndrome – posterior rotation</p> <p>Jequier syndrome – large, crumpled</p> <p>Lin–Gettig – small, external canal stenosis (all)</p> <p>Megalocornea skeletal anomalies – large</p> <p>Nevo syndrome – large, low-set</p> <p>Oculo-auriculovertebral spectrum</p> <p>Ohdo blepharophimosis</p> <p>Oto-onychoperroneal syndrome – unfolded ears, prominent antihelix and cues, no lobule</p> <p>PHAVER syndrome – simple, over-folded, notch, prominent antihelix, conductive deafness</p> <p>van den Ende–Gupta syndrome – large ears</p> <p><b>Eye Anomaly (see Ophthalmology)</b></p> <p>Aarskog syndrome – ptosis, hypertelorism (freq.)</p> <p>Aase–Smith I syndrome – ptosis, decreased eye movement</p> <p>Alkuraya syndrome – ophthalmoplegia</p> <p>Antley–Bixler syndrome – proptotic</p> <p>Bartsocas–Papavasiliou syndrome – ankyloblepharon</p> <p>Blepharophimosis, MR, Dandy–Walker – blepharophimosis</p> <p>Bohring–Opitz syndrome – prominent</p> <p>Bowen–Conradi syndrome – cloudy cornea, congenital glaucoma, large cornea</p> <p>BRESHECK – microphthalmia</p> <p>Camptodactyly, Guadalajara type I – microcornea, microphthalmia</p> <p>Camptodactyly, Kilic type – myopia, ptosis, medial fibrosis</p> <p>Carbohydrate-deficient glycoprotein syndrome – retinitis pigmentation</p> <p>Chondrodysplasia punctata, rhizomelic – cataract</p> <p>COFS syndrome – cataracts, microphthalmia, retinal pigmentation</p> <p>Conradi–Hünemann syndrome – cataracts, hypertelorism</p> <p>Contractural arachnodactyly – microphthalmia</p> <p>Distal arthrogryposis 2B – ophthalmoplegia, deep-set, ptosis</p> <p>Duane's retraction syndrome with contractures – inability to abduct the eye, narrow palpebral fissure</p> <p>Dundar–Sonoda syndrome – blepharophimosis, deep-set, short palpebral fissure</p> <p>Ectodermal dysplasia with cleft palate – blepharophimosis, develop hyperopia, amblyopia</p> <p>Ectodermal involvement with caudal appendage – blepharophimosis</p> <p>Fetal alcohol syndrome – short palpebral fissure</p> <p>Freeman–Sheldon syndrome – ptosis</p> <p>Fryns syndrome – cloudy cornea</p> <p>Fukuyama congenital muscular dystrophy – optic atrophy</p> <p>Jequier syndrome – hypertelorism, puffy eyelids, coloboma of eyelid</p> <p>King–Denborough syndrome – ptosis</p> <p>Kniest syndrome – myopia</p> <p>Larsen syndrome – hypertelorism</p> <p>Lerman–Sagie syndrome – deep-set eyes</p> <p>Lenz–Majewski – hypertelorism, lacrimal duct stenosis, prominent eyes</p> <p>Lin–Gettig – hypertelorism, small palpebral fissures (all)</p> <p>Mietens syndrome – corneal opacity, strabismus, nystagmus</p> <p>Marden–Walker syndrome – blepharophimosis, ptosis</p> <p>Marfan syndrome – dislocated lens, myopia</p> <p>Martolf syndrome – cataracts, microphthalmia</p> <p>Maternal hyperthermia – microphthalmia</p>	<p>Megalocornea and skeletal anomalies – megalocornea</p> <p>Möbius syndrome – lack of eye movement</p> <p>Moore–Weaver syndrome – antimongoloid slant, hypertelorism, short palpebral fissures</p> <p>Multiple pterygium syndrome–Escobar – antimongoloid slant, ptosis</p> <p>Myelinopathies – ophthalmoplegia</p> <p>Myopathies – ophthalmoplegia, ptosis</p> <p>Myotonic dystrophy congenital – cataracts, ptosis</p> <p>Neu–Laxova syndrome – open eyes, hypertelorism, exophthalmos</p> <p>Nevo syndrome – short palpebral fissures, deep-set, myopia, squint</p> <p>Oculodentodigital syndrome – sunken eyes, small, microphthalmia</p> <p>Ohdo blepharophimosis</p> <p>Ophthalmomandibulomelic dysplasia – corneal opacities</p> <p>Ophthalmoplegia, retinitis pigmentosa, mental retardation</p> <p>Osteogenesis imperfect – blue sclera</p> <p>Oto-onychoperroneal – persistent membrane, coloboma of retina</p> <p>PEHO syndrome – optic atrophy</p> <p>Phosphofructokinase deficiency – cloudy cornea</p> <p>Popliteal pterygium syndrome – ankyloblepharon</p> <p>Restrictive dermopathy – open eyes</p> <p>Ritscher–Schinzel – ocular coloboma</p> <p>Schwartz–Jampel syndrome – myopia, blepharophimosis</p> <p>Shalev-type distal arthrogryposis – ptosis</p> <p>Spastic paraplegia (Goldblatt syndrome) – optic atrophy</p> <p>Spondyloepiphyseal dysplasia – myopia</p> <p>van den Ende–Gupta syndrome – blepharophimosis</p> <p>Waardenburg–Klein syndrome – blepharophimosis, heterochromia iris, displaced inner canthus</p> <p>Walker–Warburg syndrome – retinal aplasia, microphthalmia, cataract</p> <p>Wieacker muscular atrophy – ocular dyspraxia</p> <p>Weill–Marchesani syndrome – dislocated lenses</p> <p>Winchester syndrome – corneal opacity</p> <p>X-linked arthrogryposis 2 – ptosis</p> <p>X-linked arthrogryposis 3 – esotropia</p> <p><b>Facial Movement Decreased</b></p> <p>Bartsocas–Papavasiliou syndrome – perioral webs</p> <p>Camptodactyly, Baraitser–London-type</p> <p>Distal arthrogryposis with facial involvement (Sheldon–Hall 2B)</p> <p>Distal arthrogryposis with ophthalmoplegia (Hall IIB, Bamshad 5)</p> <p>Freeman–Sheldon syndrome – pursed mouth, “11” on chin</p> <p>Hanhart syndrome – Möbius (occasional)</p> <p>King–Denborough syndrome – Noonan-like</p> <p>Marden–Walker syndrome</p> <p>Maternal misoprostol – Möbius</p> <p>Maternal myasthenia gravis</p> <p>Möbius syndrome – facial diplegia</p> <p>Multiple pterygium Escobar</p> <p>Multiple pterygium malignant hyperthermia</p> <p>Myelinopathies</p> <p>Myopathies</p> <p>Myotonic dystrophy congenita</p> <p>Schwartz–Jampel syndrome – pursed lips, small mouth</p> <p>Shalev-type distal arthrogryposis</p> <p>Stiff man/stiff baby – alert, tense face</p> <p>Zellweger syndrome</p> <p><b>Feeding Problems – Major</b></p> <p>(most CNS involved types of arthrogryposis have feeding problems)</p> <p>Crisponi syndrome</p>

**TABLE 161-9 Specific Organ or Area of Involvement in Various Disorders with Arthrogryposis (Congenital Contractures)—Cont'd**

<p>Diastrophic dysplasia Ectodermal dysplasia with cardiomyopathy – kyphosis King–Denborough syndrome Larsen syndrome – vertebral defects Marden–Walker – kyphoscoliosis Maternal myasthenia gravis Megalocornea and skeletal anomalies – gibbus Metatrophic dysplasia Multiple pterygium syndrome Escobar – lumbar lordosis Multiple pterygium syndrome malignant hyperthermia – scoliosis crouching stance Myelinopathies Myopathies Nevo syndrome – cervical hypolordosis Parastremmatic dysplasia Ritscher–Schinzel syndrome Sotos-like – kyphosis Stiff man/stiff baby syndrome X-linked arthrogryposis I X-linked arthrogryposis 5 <b>Seizures</b> Aase–Smith I syndrome – rare Basal ganglion disease Bixler microcephaly BRESHECK “C” syndrome variant – frequent CAD – 1/3 Dandy–Walker, MR, basal ganglion disease FG syndrome King–Denborough syndrome Maternal hyperthermia Miller–Dieker syndrome Mitochondrial defects PEHO syndrome – hypsarrhythmia Phosphofructokinase deficiency Saul–Wilson skeletal dysplasia Tuberous sclerosis X-linked arthrogryposis, type 1 (anterior horn cell loss) <b>Shin Dimples</b> Angulation of long bones Autosomal recessive arthrogryposis, inherited type Campomelic dysplasia X-linked arthrogryposis, type 3 <b>Skin, Hair, and Nails</b> Aarskog syndrome – scalp defects rare Absence of dermal ridges – milia, dry skin, dystrophic nails Amyoplasia – stork mark, hemangiomas (5%) Bartsocas–Papas syndrome – abnormal hypoplastic skin around the mouth and anus BRESHECK – alopecia, hyperkeratosis, with normal sweat glands “C” syndrome variant – redundant skin, hirsute, midline facial hemangioma Camptodactyly, London – ichthyosis Carbohydrate-deficient glycoprotein syndrome – abnormal fat distribution Conradi–Hünemann syndrome – alopecia, folliculitis, atrophoderma, patchy skin Deafness and camptodactyly (DA6) – dry skin</p>	<p>Ectodermal dysplasia and cardiomyopathy – woolly, sparse hair; dry skin; brittle nails Ectodermal dysplasia and contractures – hyperkeratosis, pili torti, dry skin Ectodermal dysplasia and clefting – sparse hair, nail hypoplasia Ectodermal involvement with caudal appendage – slow-growing hair Ehlers–Danlos VIII – wrinkling skin, atrophic scar Ehlers–Danlos VIB2 – hyperextensible, bruisable, ichthyosis Gaucher, infantile – ichthyosis Kuskokwim syndrome – pigmented nevi Johnson hyperkeratosis and decreased posterior column Lenz–Majewski syndrome – thin skin with prominent vessels, wrinkles Leprechaunism – loose, dry skin; hirsutism Nail–patella syndrome – nail dysplasia Neurofibromatosis – café au lait, neurofibromas Neu–Laxova syndrome – constrictive, ichthyotic skin Nevo syndrome – edema, soft skin, fragile Oto–onychoponeal syndrome – absent or dysplastic nails Popliteal pterygium syndrome, Gorlin type – absent nails and lip webs Potter syndrome – redundant, wrinkled, increased creases Proteus syndrome – lipomas, hamartomas, hemangiomas, mottling Puritic–Murray syndrome – fibromatosis, skin lesions, skin infections Restrictive dermopathy – tight, thin Schinzel–Giedion syndrome – hypertrichosis, abundant skin Tuberous sclerosis – adenoma, depigmentation, shagreen patches Ullrich congenital myopathy – rough skin Waardenburg–Klein syndrome – white patches, early graying, pigmentary anomalies Winchester syndrome – malar flush, thick facial skin <b>Syndactyly</b> Aarskog syndrome – mild in hands and feet, very frequent Absence of dermal ridges Amyoplasia Bartsocas–Papas syndrome – mitten hand Hanhart syndrome Neu–Laxova syndrome Pfeiffer syndrome Poland syndrome Smith–Lemli–Opitz syndrome <b>Teeth (see Dental)</b> <b>Thumbs – Proximal or Abnormal</b> Adducted thumbs syndrome Clasped thumb and mental retardation Clasped thumb syndrome Deafness and camptodactyly Diastrophic dysplasia – “hitchhiker” thumb Dundar–Sonoda syndrome – adducted thumbs Fryns syndrome – digitalization of thumb Hand–foot–uterus syndrome – small and small big toes Holt–Oram syndrome – small Jequier – broad thumbs Martsolf syndrome MASA syndrome Nemaline myopathy – short first metacarpal</p>
--	---

Continued

**TABLE 161-9 Specific Organ or Area of Involvement in Various Disorders with Arthrogryposis (Congenital Contractures)—Cont'd**

Oral–cranial–digital syndrome (Juberg–Hayward syndrome) – hypoplastic, distal thumb

Pfeiffer cardiocranial synostosis – broad distal phalanges

PHAVER syndrome – missing, digitalized

X-linked arthrogryposis, type 2

#### **Tongue**

Hanhart syndrome – small or absent

Möbius syndrome – hypoplastic

Wieacker syndrome – muscular atrophy, dyspraxia

#### **Trismus**

Aase–Smith I syndrome – frequent

Amyoplasia – rarely

Carney variant

Crisponi syndrome

Distal arthrogryposis IIE

Distal arthrogryposis – Sheldon–Hall

Freeman–Sheldon syndrome

Trismus–pseudocamptodactyly

#### **Tumors**

Aase–Smith – neuroblastoma

Hunter–MacDonald camptodactyly – meningiomas

Proteus – hamartomas, lipomas, hemangiomas

Puretic–Murray – multiple fibromas, other tumors matoses

Neurofibromatosis – neurofibromas

Sacral agenesis – presacral tumor

Schinz–Giedion – neuroectodermal sacrococcygeal tumor

Tuberous sclerosis – glioma angioma, phacoma

#### **Umbilical**

Aarskog–Scott syndrome – defect

Lin–Gettig – pigmentation, hernia

Shalev-type DA – long

#### **Uterine Anomaly**

Acrorenalmandibular syndrome

Hand–foot–uterus – duplications, structural anomalies

#### **Vascular Defects**

Amyoplasia – GI, distal digits

Attempted termination of pregnancy

Fowler syndrome – proliferative vasculopathy

Hanhart syndrome

Liebenburg syndrome – distal digit loss

Maternal misoprostol

#### **Vertebral Anomaly**

Aarskog syndrome – particularly cervical (freq.)

Antley–Bixler syndrome – fused, probably

“C” syndrome variant – segmentation (occ.)

CAD – agenesis coccyx and sacrum, flattening

Diastrophic dysplasia – cervical instability

Dyssegmental dysplasia – variable size, segmental dysplasia

Focal femoral dysplasia – vertebral anomalies

Larsen syndrome – cervical instability, vertebral defects

Metatrophic dysplasia – cervical instability, progressive change

Mitochondrial defects

Multiple pterygium syndrome, Escobar type – segmentation defects

PHAVER syndrome – butterfly, hemi-, webbing

Ritscher–Schinzel syndrome

Sacral agenesis

Spondylothoracic dysostosis – crablike segmentation defect

VATER association

X-linked arthrogryposis, Zori

#### **Webbing, Includes Pterygium (see also Syndactyly)**

Absence of fingerprints – mild finger webbing

Acrorenal–mandibulo–uterine syndrome

Amyoplasia – mild

Antecubital pterygium (Shin Shun)

Bartsocas–Papas – popliteal

Bruck syndrome – progressive

Distal arthrogryposis with facial involvement (Sheldon–Hall) – mild

King–Denborough syndrome

Kuskokwim syndrome

Moore–Weaver syndrome – neck webbing

Multiple pterygium syndrome, Escobar type – progressive

Multiple pterygium syndrome lethal – severe

Shalev-type of DA

Multiple pterygium syndrome with malignant hyperthermia – neck webbing

Nail–patella – occasional elbow webbing

Oto–onychoperroneal syndrome

PHAVER syndrome – elbow, shoulder

Popliteal pterygium syndrome, Gorlin type – knee, along popliteal edge with neurovascular bundle, intraoral web

Spondylothoracic dystrophy

AD = autosomal dominant; AF = anterior fontanelle; AR = autosomal recessive; ARC = arthrogryposis, renal dysfunction, cholestasis syndrome; ASD = atrial septal defect; BA = bowel atresia; CHD = congenital heart defect; CNS = central nervous system; DA = distal arthrogryposis; GI = gastrointestinal; IA = intestinal atresia; LCCS = lethal congenital contracture syndrome; PS = pulmonary stenosis; TE = tracheoesophageal; TEF = tracheoesophageal fistula; TMJ = temporomandibular joint; VSD = ventricular septal defect.

TABLE 161-11 Distal Arthrogryposes: Differential Diagnosis with Additional Types of Distal Arthrogryposis (Not Including Camptodactyly Syndromes – See Table 161-13)				
Hall Classification	Bamshad Classification			Genes
I	1.	Distal (AD, simplex), some families mainly involve hands (includes digitotarsal dysmorphism)	1A	<i>TPM2, MYBPC1, TNN12, MYH3</i>
IIA	2.	Gordon's syndrome (AD, short stature +/- CP)	3	
IIB	3.	AD with ophthalmoplegia – may not be congenital; one family included retinal pigment changes and MR; may have Dandy-Walker in family	5	
IIC	4.	Clefting, AD, trismus, may be Gordon syndrome		
IID	5.	Scoliosis (may include Goodman syndrome)	4	
IIE	6.	Trismus and unusual hand ~ amyoplasia spectrum		
	7.	Freeman-Sheldon syndrome	2A	<i>MYH3</i>
	8.	Sheldon-Hall (includes Moore-Weaver syndrome)	2B	<i>TNNT3, TNN12, MYH3, TPM2</i>
	9.	Sheldon-Hall look-alike	2C	
	10.	Deafness, camptodactyly syndrome	6	<i>FGFR3</i>
	11.	Trismus pseudocamptodactyly (Beal's syndrome, Kentucky Dutch syndrome)	7	<i>MYH8</i>
	12.	AD, multiple pterygium	8	
	13.	Contractural arachnodactyly	9	Fibrillin 2
	14.	Distal with plantar flexion contractures	10	
	15.	Dundar-Sonoda syndrome (MR, unusual face)		
	16.	Absent teeth and abnormal facies (may be Sheldon-Hall)		
	17.	Chitayat syndrome (AR, MR, hypopituitary)		
	18.	X-linked distal arthrogryposis		
	19.	Shalev syndrome (AR, mainly upper limbs, ptosis)		

AD = autosomal dominant; AR = autosomal recessive; CP = cleft palate; MR = mental retardation.

**TABLE 161-12 Multiple Pterygium Syndromes**

1. Antecubital Pterygium Syndrome (Shin Shun) AD
2. Popliteal Pterygium Syndrome (IRF6) AD
3. Pterygium Autosomal Dominant (also DA 8)
4. Bartsocas-Papas Syndrome (RIPK4) AR
5. Lethal Multiple Pterygium Syndrome (Gillin-Pryce-Davies Type) (Embryonic neuroreceptor unit mutations ) AR
6. Myasthenia Gravis Congenital - AR
7. Antibodies to embryonic neuroreceptor subunits - maternal
8. Multiple Pterygium Syndrome Escobar (CHRNA7, 2q37, etc.) AR
9. Multiple Pterygium Syndrome with Malignant Hyperthermia AR
10. Pterygium with Ectodermal Dysplasia AR
11. Skin Webbing with Cutis Laxa AR
12. X-linked variety of Pterygium Syndrome
13. Shalev type involving mainly upper limbs with ptosis AR
14. Other syndromes with pterygia
  - a. Chromosomal disorders
  - b. Escobar with creased tongue AR
  - c. Fetal akinesia sequence disorders
  - d. Haspelagh syndrome
  - e. Kuskokwim syndrome (FKBP10) AR
  - f. Median report chin webs
  - g. Mietens syndrome
  - h. Myopathies
  - i. Pfeiffer syndrome (FGFR2) AD
  - j. Sacral agenesis
  - k. Severe Amyoplasia
  - l. Williams

AD, autosomal dominant; AR, autosomal recessive; DA, distal arthrogryposis

Hall, J.G. Revisiting limb pterygium syndromes (Paper submitted for Festschrift in honour of Professor Christos Bartsocas). For the sake of science. 2012, ZHTA Medical Publications, Athens, Greece, Honorary volume for Christos S. Bartsocas, 373-385.

**TABLE 161-13** Types of Camptodactyly Which are Variable Within Families and Often Involve Lower Limbs

<b>Autosomal Dominant Syndromes</b>
Welch and Temtamy (classic, isolated)
Baraitser, Lizcarno (mainly uppers, scoliosis, torticollis, cervical vertebral fusion)
Christian (platyspondylia, vertebral fusions, carpal and tarsal fusions)
Deafness and camptodactyly (tall stature)
Emery Nelson (flat face, abnormal nose)
Guadalajara III (spinal defects, hypertelorism, brain structural anomaly)
Hunter MacDonald (scoliosis, deafness, congenital heart defects, and meningioma)
<b>Autosomal Recessive Syndromes</b>
ARC (arthropathy, pericarditis)
Guion arthropathy, Almeida (MR, skin tag, CP, and arachnodactyly)
Guadalajara I (facies unusual, thoracoskeletal abnormalities, microcephaly)
Guadalajara II (short neck, hypoplastic patellae, DD, microcephaly)
Ichthyosis and Windmill–Vane (Baraitser) (ichthyosis, seizures – possibly two types)
Lin–Gettig syndrome (agenesis corpus callosum, craniosynostosis, MR)
Pagon Gallop (MR, obesity, osteoporosis, large epiphyses)
Pointer syndrome (extended second digit)
Richeiri–Costa I (lethal, hypoplastic digits)
Richeiri–Costa II (MR, long face, cleft lip)
Rozin and Kilic (scoliosis, lateral rectus fibrosis)
Tel–Hashomer (short stature, normal IQ, prominent forehead, hypertelorism)
van den Ende–Gupta Syndrome (arachnodactyly, blepharophimosis, “surprised” facies)
<b>X-linked Syndromes</b>
Aarskog syndrome

ARC = arthrogryposis, renal dysfunction, cholestasis syndrome; CP = cleft palate; DD = developmental delay; IQ = intelligence quotient; MR = mental retardation.

**TABLE 161-14** Fetal Akinesia Sequence

(1)	Classic Pena–Shokeir syndrome
(2)	Lower motor neuron disorder with generalized decrease in anterior horn cells (Chen type)
(3)	Lethal congenital contractures syndrome type 1
(4)	Lethal congenital contractures syndrome type 2
(5)	Lethal congenital contractures syndrome type 3
(6)	Lethal lower motor neuron deficiency with degeneration
(7)	Families with apparent increase in monozygotic twinning
(8)	Normal <i>in utero</i> growth, macrocephaly and Pena–Shokeir phenotype (Lammer type)
(9)	Absence of pyramidal cells, immature CNS development, adducted thumbs, kyphoscoliosis, and severe pulmonary hypoplasia (Biscegli type)
(10)	CNS dysgenesis and degeneration, seizures, trismus, endocrine hyperplasia, and abdominal wall herniation (Erdl type)
(11)	Skeletal muscle maturation defect
(12)	Pyramidal tract degeneration
(13)	<i>In utero</i> seizures, scoliosis, together with cerebral and cerebellar hypoplasia in males (Persutte type)
(14)	Microphthalmia, microtia, and normal birth size (Thomas type)
(15)	Olivo–ponto–cerebellar hypoplasia
(16)	Failure to myelinate peripheral nerves – many genes
(17)	Holoprosencephaly with hypokinesia and congenital contractures in an X-linked recessive pattern of inheritance
(18)	Hydranencephaly, calcification of basal ganglion and proliferative vasculopathy (Fowler type)
(19)	Calcification of leptomeninges, the surface of cerebral convolutions, neurons, muscles, and vessels (Illum type)
(20)	Familial intrauterine anoxia and/or ischemia.

CNS = central nervous system.

(Hall, J. G., Pena–Shokeir Phenotype (Fetal Akinesia Deformation Sequence Revisited). *Birth Defects Res. A Clin. Mol. Teratol.* **2009**, 85, 677–694).

**TABLE 161-15 Arthrogryposis Syndromes Which Usually or Often Present with Only Upper or Lower Limb Involvement****Upper Limbs**

Agenesis of corpus callosum, severe MR, camptodactyly (Lin–Gettig Syndrome)  
 Amyoplasia – upper limb only  
 Antecubital pterygium syndrome (Shin Shun)  
 Autosomal dominant pterygium  
 Baraitser–London camptodactyly  
 Guadalajara camptodactyly III  
 Hunter–MacDonald syndrome  
 Liedenbug syndrome  
 Rozin and Kilic camptodactyly (ptosis, ophthalmoplegia)  
 Shalev-type arthrogryposis (ptosis, umbilical hernia)  
 Urban–Rogers–Meyer syndrome  
 X-linked resolving arthrogryposis

**Lower Limbs**

Amyoplasia lower limbs only  
 Angulation of long bone syndrome  
 Fuhrmann syndrome  
 Genitopatellar syndrome  
 Kuskokwim syndrome  
 Lower limb AD (Fleury type)  
 Lower limb AR (Ray/Sarralde)  
 Lower limb X-linked, caudal dysplasia  
 Meningomyelocele/spina bifida/spinal dysraphism  
 Prenatal early amniocentesis or CVS

AD = autosomal dominant; AR = autosomal recessive; CVS = chorionic villus sampling; MR = mental retardation.

**TABLE 161-16 Metabolic Disorders Presenting with Arthrogryposis**

Name	Gene
Adenylosuccinate lyase deficiency – AR (microcephaly, hypotonia, self-mutilation)	<i>ADSL</i>
ARC (arthrogryposis, renal dysfunction, cholestasis syndrome; Nezeloff syndrome) – AR (cholestasis, renal (Fanconi), hypotonia)	<i>VPS33B, VIPAR</i>
Carbohydrate-deficient glycoprotein syndrome – AR (hydrops, unusual fat, liver anomalies)	<i>PMM2, PM11</i>
Gaucher disease – perinatal lethal – AR (hydrops, hepatosplenomegaly, ichthyosis)	<i>GBA</i>
Glycogen storage IV – AR (hydrops, fetal akinesia, muscle deposits)	<i>GLE1</i>
Juvenile hyaline fibromatosis (Puretic–Murray syndrome) – AR (gingival hypertrophy, fibromas, infections, pain)	<i>CMG2, ANTXR2</i>
Phosphofructokinase deficiency (glycogen storage VII) – AR (seizures, corneal cloudy, hepatosplenomegaly)	<i>PFKM</i>
Zellweger syndrome – AR (FIT, hypotonia, prominent forehead)	Many <i>PEX</i> genes

AR = autosomal recessive; also mitochondrial disorders, myopathies, myelinopathies, malignant hyperthermia disorders, skeletal dysplasias, and other storage disorders.

**TABLE 161-17 X-linked Syndromes with Arthrogryposis**

Definite			
Entity	MIM#	Location	Gene
XAMC-I; Severe spinal muscular atrophy (SMA2)	301830	Xp11.23	<i>UBE1</i> [now <i>UBA1</i> ]
Aarskog syndrome (Aarskog–Scott syndrome, Faciodigitogenital syndrome)	305400	Xp11.22	<i>FGD1</i> ( <i>Rho/Rac</i> )
CASK syndrome	300749	Xp11.4	<i>CASK</i>

Spranger, J. W.; Brill, P. W.; Nishimura, G.; Superti-Furga, A.; Unger, S. *Bone Dysplasias: An Atlas of Genetic Disorders of Skeletal Development*, 3rd ed.; Oxford University Press: New York, NY, 2012.

that are associated with congenital contractures. Chromosome studies or better yet CGH array should be done in any child with arthrogryposis and mental disability. There is obvious overlap between these categories because some individuals with a condition may only have involvement of the limbs while others in the same family or with the same condition may have more widespread involvement. Similarly, in some conditions with congenital joint contractures, a characteristic feature is mental disability, but there may be affected individuals who do not have mental disability. Nevertheless, we have found this approach to be the most useful for the clinician. It is impossible to describe in detail all the conditions with congenital contractures, but it seems appropriate to emphasize several of the frequently observed conditions under the three categories. As gene pathways are being identified, conditions may be classified as being related to muscle proteins, muscle metabolism, and homeostasis proteins, proteins involved in development and function of lower motor neurons, proteins involved in skeletal and cartilage systems and differentiation, proteins involved in nervous system growth, regulation and differentiation, proteins involved in peroxisome organization, excision repair proteins, proteins involved in cellular and developmental functions, proteins involved in metabolic pathways and “others” (84). Alternatively, if the structural area of abnormality can be identified, multiple congenital contractures can be classified as cerebral, spinal, neuromuscular connection, myopathy, connective tissue, or limitation of movement. Classification is now possible for over half of cases of arthrogryposis. Understanding etiology enhances the chance for prevention and therapy. However, for now, a clinical approach is necessary.

## 161.4 FREQUENTLY OBSERVED CONDITIONS

### 161.4.1 Primarily Limb Involvement

**161.4.1.1 Amyoplasia.** Amyoplasia is the most common condition with severe multiple congenital contractures and is referred to as “classical arthrogryposis” by most orthopedic specialists. One-third of all patients in our large study of congenital contractures had amyoplasia (31,368,370,752). Many forms of arthrogryposis have decreased muscle mass, hypoplastic muscle, or loss of muscle; however, when the term Amyoplasia is used in this chapter, it is meant to refer only to this specific condition. Care should be exercised when using this diagnostic term since it implies a specific natural history, recurrence risk, and etiology.

Amyoplasia is characterized by very specific positioning, usually with symmetrical limb involvement, and usually involves all four limbs; however, occasionally only the arms or only the legs are involved. Affected individuals have fibrous bands and fatty tissue where muscles would normally be, suggesting that the muscle or muscle anlage was formed embryologically but failed to develop in a normal way. These patients usually have firmly fixed joints (Figure 161-1) with a fusiform or cylindrical shape to the limbs in the newborn period, suggesting that the limitation of movement has been present for many months. Usually flexion creases are shallow or not present, suggesting lack of movement occurs earlier than 14 weeks of embryologic development. The feet are almost always in equinovarus position, the wrists are almost always flexed, the shoulders are internally rotated and sloping, and the elbows are extended and fixed at 180 degrees at birth, but may develop some flexion with

**FIGURE 161-1** Amyoplasia in a newborn. Note alert expression, characteristic internally rotated shoulders with decreased muscle mass, extended elbows, wrist and hand contractures, equinovarus deformities of the feet, dimples and flexion contractures at the knees. The face is round, the nose short and upturned; there is a midline facial hemangioma.

growth and physical therapy. Rarely, the loss of functional muscle is so severe that some elbow flexion occurs *in utero* (the bones grow in length, but the fibrous muscles do not, leading to elbow flexion), but these individuals are always severe with marked muscle hypoplasia. There may be slight webbing of skin across the hips, knees (if flexed), and axillae. The hips may be flexed or extended in abduction or adduction and are often dislocated. The knees may be fixed in extension or in flexion. Sensation is intact. Deep dimples are most often present over joints. The affected limbs appear mildly shortened.

Early physical therapy is extremely important to loosen contractures that are present at birth and thereby give whatever muscle is present a chance to strengthen, rather than atrophy. The best results of mobilizing contractures in Amyoplasia seems to be in the first 3 to 4 months. However, of course, care must be taken not to fracture bones that are osteoporotic. Surgery is important to align the limbs in positions of function (8,38,52,188,1004). Magnetic resonance or ultrasound (112) imaging prior to surgery may provide an indication of the muscle mass present. In many cases, an unusual angle of the joints or flattening of the joint surface needs to be taken into consideration when doing physical therapy.

About 90% of individuals affected with Amyoplasia have no other system involvement; however, a variety of

other anomalies can be seen in Amyoplasia. Ten percent of patients have abdominal wall defects (gastroschisis, lateral wall hernias) or bowel atresia (66,187). There is a very high frequency of “stork mark”-type birthmarks over the midface. The face is usually somewhat round and flat with mild micrognathia. Mild trismus may be present.

About 5% of the cases have had amniotic bands or digit reduction anomalies on one or more limbs. A few children have a decrease in size of the distal digits; many have mild syndactyly or webbing of the digits. Often at birth, but definitely with time, there is undergrowth of an affected limb, much like the disuse atrophy seen in polio. Intelligence is usually within normal limits, unless there was trauma and/or anoxia at birth. In fact, families often feel that affected children are brighter than average. Rare cases of growth hormone deficiency have been seen.

There appears to be an increased incidence of Amyoplasia in one of monozygotic twins (with one normal twin and one affected twin). Often the affected twin has only arms or only legs involved (186).

It appears that all cases of Amyoplasia have been sporadic, and many affected individuals have reproduced, having unaffected children. Since Amyoplasia occurs in approximately 1 in 10,000 live births, recurrence could occur by chance alone. Prenatal diagnosis in subsequent pregnancies can be offered for reassurance using serial real-time ultrasound to detect normal limb movement. Most probably, the condition is secondary to some type of vascular compromise during the first trimester. It is likely that the timing is related to the degree of involvement.

**161.4.1.2 Distal Arthrogryposes.** Many types of arthrogryposis have distal involvement (113,114) (Table 161-11). Distal arthrogryposis type 1 is characterized by a very specific positioning of hands in the newborn period and primarily distal contractures of the limbs (114,115) (Figure 161-2). Other conditions have distal contractures, but this particular type has autosomal dominant inheritance and is characterized by being quite responsive to physical therapy. The hand positioning in the newborn is similar to that seen in trisomy 18, with a clenched fist and overlapping fingers (Figure 161-3). With physical therapy, the hand usually opens up, but there is often some residual ulnar drift of the fingers. Foot positioning is variable. Both equinovarus and calcaneovalgus feet have been seen within the same family, as well as in a single individual. Both the hand and foot abnormalities appear to have misplaced tendons; there are several cases in which this has been documented at surgery. Occasionally, affected family members have contractures of the hips, knees, and elbows. There can be marked variability in the involvement within a family.

Some individuals with primarily distal involvement of the limbs have been reported as cases of familial campodactyly, (Table 161-13) contractural arachnodactyly,

**FIGURE 161-2** Distal arthrogryposis type I in a newborn. Note pre-dominant distal contractures, with overlapping finger contractures, ulnar deviation, and clubfeet.

**FIGURE 161-3** Distal arthrogryposis type I newborn hand. Note clenched fist and overlapping fingers similar to hand position in trisomy 18.

or Freeman–Sheldon syndrome because of the similarity of distal limb involvement and positioning. Several sporadic cases have been associated with advanced paternal age, suggesting new dominant mutations. Family studies are very helpful because observing the variability within a family allows proper classification (113,116–123a). Molecular testing is available for many of these families related to sarcolemmal proteins.

Bamshad et al. (116) have suggested a division of distal arthrogryposes into several categories because specific gene mutations involving components of fast twitch muscle have been identified in families (Table 161-11). Some families tend to have facial

muscle involvement with limitation of facial movement and/or ptosis (Bamshad type 2B) while other families lack facial involvement (Hall type I (114), Bamshad type 1 (99)).

Most affected individuals with distal arthrogryposis type 1 have no other nonorthopedic anomalies; however, several subcategories of distal arthrogryposis may have additional physical abnormalities. It is not clear whether these are totally distinct categories or whether several subtypes can be seen within the same family (121). We list them under Tables 161-2 and 161-3. One of the subtypes is often referred to as Gordon syndrome (122) (Hall type IIA, Bamshad type 3) and has the additional features of cleft palate and short stature in some affected family members (~30–50%). The degree of short stature and severity of clefting in an affected individual seems to be proportionate to the severity of involvement of the joints.

Another category of distal arthrogryposis (Hall type IIB, Bamshad type 5) (24,113,114) has very firm muscles that may show ragged red fibers on biopsy. Ophthalmoplegia develops in this condition during childhood. Eyes are deep set and the faces are somewhat elfin. Autosomal dominant inheritance has been seen in several families with male-to-male transmission (114,324,325,328,329,995). Dimples and lack of flexion creases on the fingers are also seen. It does not appear to be progressive or to have degeneration; however, pulmonary involvement may be progressive.

Patients with another type of distal arthrogryposis primarily involving distal limbs (Hall type IIC) (113,114,121,123a) also have cleft lip. Severe scoliosis is seen in some families with distal contractures (Hall type IID, Bamshad type 4) (113,114,124).

Still another subcategory of distal arthrogryposis (Hall type IIE), is important to identify because it has limitation of jaw movement (trismus) with or without micrognathia in association with more generalized congenital contractures (114). The hand contractures are in an unusual position with flexion of the wrist, hyperextension of the metacarpophalangeal joint, and flexion of the other finger joints. Approximately one-third of these cases have mild mental retardation; all of these cases appear to be sporadic. The trismus can be severe, leading to feeding problems and possibly respiratory compromise. There is a higher than expected incidence of other joint anomalies within the family, and it is not entirely clear whether the condition is sporadic. It has been designated distal arthrogryposis with trismus (Hall type IIE) for want of a better term (114).

All forms of distal arthrogryposis seem relatively responsive to physical therapy and surgical procedures. Some individuals and families are so mildly affected that one is not able to recognize any residual deformity, and only by talking to the grandparents is it found that there were mild contractures at birth.

### 161.4.2 Limb Involvement with Other System Abnormalities

The second major category of conditions with congenital contractures is that in which the contractures of the limbs are in association with anomalies or malformations of other parts of the body (see Table 161-3). Some of the distal arthrogryposes fit in this category because of other system involvement.

**161.4.2.1 Freeman–Sheldon Syndrome.** Perhaps the best known of these is Freeman–Sheldon syndrome, or whistling face syndrome (also known as craniocarpotarsal dystrophy), in which there are congenital contractures, primarily of the hands and feet with overlapping fingers and ulnar deviation, in association with pursed mouth and limitation of facial movement secondary to fibrosis of facial muscles (Figure 161-4). There may be a characteristic H-shaped connective tissue band on the chin. Affected individuals tend to have long faces with markedly decreased facial movement. Individuals with Freeman–Sheldon syndrome may also have scoliosis, midface hypoplasia, lateral coloboma of the alae nasi, ptosis, and an antimongoloid slant of the eyes. Freeman–Sheldon syndrome may be more resistant to therapy than other forms of distal arthrogryposis (125) even though

**FIGURE 161-4** Freeman–Sheldon or whistling face syndrome in father and daughter. Note hand and foot contractures; more severe in the father, who has a very small left foot. The eyes are deeply set with an antimongoloid slant, the mouth is small, and there is a mild groove in the chin. Both have short stature and short necks.

the responsible genes overlap. It is clear that there is interfamilial and intrafamilial variability, but that autosomal dominant inheritance is the most common mode of inheritance. The gene for the autosomal dominant type has been identified to be MYH3, the embryonic form of the myosin heavy chain (106).

**161.4.2.2 Contractural Arachnodactyly and Congenital Marfan Syndrome.** Contractural arachnodactyly is a well-defined condition with autosomal dominant inheritance characterized by congenital contractures, long thin extremities, crumpling of the top of the helix of the ear, and kyphoscoliosis (126a). Various chest deformities are seen as well, with pectus excavatum or carinatum. Marked inter- and intra-familial variability is seen. Less than 10% of cases appear to be severely involved with progressive scoliosis. The other 90% of cases seem to improve with age. There has been a suggestion of overlap with congenital severe Marfan syndrome, in that some individuals with contractural arachnodactyly may have structural abnormalities of the heart with mitral valve prolapse and/or aortic aneurysms (128) (see Chapter 153). This is not surprising since both conditions involve fibrillin genes: fibrillin I (15q21.1) in Marfan syndrome and fibrillin II (5q23–31) in contractural arachnodactyly (129). Severely affected sporadic newborns have been reported with advanced bone age and additional gastrointestinal or vertebral anomalies (130).

**161.4.2.3 Pterygium Syndromes.** Many newborns and children with arthrogryposis have webs (or pterygia) across the joints that have limited movement. However, several specific conditions with marked webbing (131,132) are seen as specific entities with consistent features in different families (Table 161-12). Many of the responsible genes have been identified.

**Multiple pterygium syndrome (Escobar type)** is characterized by flexion contractures at birth. At birth, webs may not be present or prominent, but with aging, webs develop at the neck, elbows, knees, and intercrural areas. Cleft palate, deafness, scoliosis, and short stature are frequently present, as well as segmentation anomalies of the vertebrae. Many cases are sporadic, but most appear to have autosomal recessive inheritance (132–134) and involve the embryonic neurotransmitter receptor subunits (135–141a). A few families have been reported with marked variability and possible dominant inheritance (142–144). This may be a progressive condition as about 20% of individuals seem to get worse as they enter puberty, with decreasing pulmonary capacity and increasing thoracic lordosis (132,134). Myopathic changes have been reported in a fairly typical case (145). The possibility of therapy now exists utilizing therapeutic doses of acetylcholine-like drugs and have worked in animal models.

**Lethal multiple pterygium syndrome (Gillin–Pryse–Davis type)** is characterized by intrauterine growth retardation, severe flexion contractures, and webs *in utero*, frequently with cystic hygromas and hydrops. Lungs are

severely hypoplastic, so that survival usually does not occur. Polyhydramnios, ocular hypertelorism, cryptorchidism, cardiac hypoplasia, and ambiguous genitalia in males are frequently seen (146). Subtypes related to bony fusions and the time during gestation when severity becomes obvious may exist (131). Apparently, most cases are autosomal recessive and can be diagnosed prenatally (147,148). However, there may be an X-linked recessive form (149). The genes involved in embryonic neurotransmitter receptor subunits are also involved in some cases, suggesting *in utero* therapy may be possible (138,150a,151).

**Popliteal pterygium syndrome (Gorlin type)** is characterized by dense webs in the popliteal area (often with the nerve and blood vessel in the edge of the web), cleft lip and palate, syndactyly, nail anomalies, reduction deformities of digits, and other contractures. It is an autosomal dominant condition with marked variability in expression (152,153). Recently, the IRF6 gene on chromosome 1q32–q41 has been found to be responsible, so prenatal diagnosis should be possible (154).

**Bartsocas–Papas syndrome (lethal popliteal web syndrome)** is characterized by severe popliteal webs, cleft lip and palate with facial clefts, hypoplasia of the nasal tip and genital area, syndactyly with missing distal digits, sparse hair, and hypoplastic teeth. It is almost always lethal, but if the newborn period is survived, intelligence appears normal. Autosomal recessive inheritance seems likely, and consanguinity, particularly with Mediterranean ancestry, has been observed (155–157a,158a). Mutations have been found in the RIPK4 gene (159).

**Multiple pterygium with malignant hyperthermia** has been observed in several families. Scoliosis, torticollis, myopathic facies, and cleft palate have been present (35,160,161). Creatinine phosphokinase (CPK) levels are not necessarily elevated, and muscle biopsy is compatible with disuse atrophy rather than a myopathy. The relationship to King syndrome is not clear because King syndrome has a Noonan phenotype with malignant hyperthermia and elevated CPKs, but congenital contractures can be seen (162).

**161.4.2.4 Chondrodysplasias.** A variety of chondrodysplasias (including campomelic dysplasia, diastrophic dysplasia, Dyggve–Melchior–Clausen dysplasia, dyssegmental dysplasia, Kniest dysplasia, Larsen syndrome, metatropic dysplasia, and osteogenesis imperfecta) also fall into this second category of congenital contractures associated with other system anomalies (163) (see Chapter 157).

### 161.4.3 Congenital Contractures with CNS Anomalies or Dysfunction and/or Lethality

The third category of conditions with congenital contractures is that in which there are congenital contractures of the limbs associated with CNS malformations

or dysfunction, and/or lethality (Figure 161-5; see Table 161-4). Many relatively rare autosomal recessive lethal conditions as well as many chromosomal anomalies fall into this category.

**161.4.3.1 Pena–Shokeir Phenotype.** Pena and Shokeir described the combination of short fixed limbs and pulmonary hypoplasia. Subsequently, many other families have been reported (16,90,164), with the additional features of intrauterine growth retardation, polyhydramnios, short umbilical cord, and unusual craniofacies being noted. This combination of features seems to be due to fetal akinesia (12), suggesting the fetus must move *in utero* to have normal development of a variety of structures. Many familial subtypes can be distinguished on the basis of CNS pathology and clinical features (see Table 161-14), suggesting that the features represent a phenotype rather than a specific diagnosis. Prenatal diagnosis is possible in these families (25,84,165,839).

**161.4.3.2 Cerebro–Oculo–Facial–Skeletal Syndrome.** Pena and Shokeir also described cerebro-oculo-facio-skeletal syndrome (COFS) (166). This has led to a great deal of confusion because abnormal eye involvement is common in lethal conditions with contractures. COFS is characterized by structural abnormalities of the brain, dysmyelination, and eye anomalies, including microphthalmia and cataracts (167). In the original family, the excision repair gene XPD has been found to be involved

**FIGURE 161-5** Congenital contractures associated with central nervous system dysfunction. Note all limbs have flexion contractures; there is microcephaly with an abnormally shaped head and an unusual facies. The infant has micro-ophthalmia, abnormally shaped ears, a thin upper lip, long philtrum, micrognathia, mild webbing, and a large inguinal hernia.

(168,169) and other excision repair gene mutations may give a similar phenotype (particularly CSA). The natural history of this degenerative condition is variable even within a family. In some families, some affected individuals are born with contractures and others are spared at birth but develop contractures later in life. Renal anomalies, other visceral anomalies, and variations in bone density can be seen. An X-linked recessive form may exist.

**161.4.3.3 Neu-Laxova Syndrome.** Neu-Laxova syndrome is a striking phenotype with dramatic contractures, intrauterine growth retardation, microcephaly, open eyes, tight ichthyotic skin, and severe CNS anomalies (170). Kyphosis, syndactyly, and hydrops are often seen. It is a lethal autosomal recessive condition and can be diagnosed prenatally (171).

**161.4.3.4 Restrictive Dermopathy.** Several recent reports describe a syndrome with contractures in which it appears that fetal skin fails to grow normally and thereby restricts movement, leading to secondary contractures. All families are compatible with autosomal recessive inheritance (172–174) and several genes have been found (175–177).

**161.4.3.5 Chromosome Anomalies.** Many chromosome anomalies can have congenital contractures (70) (Table 161-5). With the advent of micro CGH arrays, many new microdeletion and microduplication syndromes are being identified, many of which have associated multiple congenital contractures. Some encompass genes already identified to be responsible for particular known types of arthrogryposis. Others effect CNS development to the detriment of *in utero* function, leading to fetal akinesia and/or hypotonia sufficient to develop secondary joint contractures. Every autosome has been implicated to be associated with arthrogryposis. There are some chromosomal disorders which seem to always have severe congenital contractures, such as trisomy 8 mosaicism and trisomy 18.

Any child with mental disability and arthrogryposis should have CGH array studies and consideration given to doing CGH on fibroblasts looking for mosaicism (which seems to be quite common in children with mental disability and arthrogryposis) (24). It should be noted that all children with arthrogryposis will have motor developmental delay due to the contractures, but if social and intellectual delay is present, then the disorders listed in Tables 161-4 and 161-5 should be considered.

**Trisomy 18** is probably the most frequent condition in this category, characterized by intrauterine growth retardation, visceral anomalies with extremely high incidence of heart disease, radial limb anomalies, short sternum, small pelvis, facial paralysis, and a typical positioning of fingers with overlapping fingers, clenched fists, and rocker-bottom feet.

**Trisomy 8 mosaicism** also frequently presents with congenital contractures and is often characterized by

absence of the patella and deep furrows in the palms or soles. Individuals with trisomy 8 mosaicism may only be identified with fibroblast karyotyping.

**Deletion 5q.** The genes for spinal muscular atrophy (SMA; Werdnig Hoffman disease) have been identified. Classical SMA has hypotonia without contractures at birth. However, deletions of 5q that involve the SMA gene may produce *in utero* hypotonia with contractures at birth. These children tend to do poorly (178).

## 161.8 SUMMARY

Multiple congenital contractures are relatively frequent and often part of recognizable syndromes. Marked heterogeneity does exist, as seen in Tables 161-2–161-7. Careful investigation should lead to a specific diagnosis in more than half the cases, allowing more specific prognostication, counseling, and therapy.

## Biography

**Dr Judith Hall**, Professor Emerita in the Departments of Pediatrics and Medical Genetics at the UBC and Children's and Women's Health Centre of BC, BC's Children's Hospital, Vancouver, is a pediatrician and clinical geneticist who has worked on birth defects and non-traditional mechanisms of disease. She has conducted clinical research for the past 35 years with a major interest in the description of natural history and identification of syndromes. Dr Hall has contributed to the understanding of the tissue-specific and time-specific nature of gene expression as well as the changes of gene expression during embryonic, fetal, and childhood development. She has served in many leadership roles, including Chair of the UBC and BC Children's Hospital Departments of Pediatrics, presidency of the American Society of Human Genetics, the Western Society of Pediatrics, and the American Pediatrics Society, as well as on numerous national and international committees and boards. She became an Officer of the Order of Canada in 1998, a Founding Fellow of the Canadian Academy of Health Sciences in 2005, and a Fellow of the Royal Society of Canada in 2011.

## Common Skeletal Deformities

William A Horton

Director of Research, Shriners Hospital for Children, Professor of Molecular and Medical Genetics,  
Oregon Health and Science University, Portland, OR, USA**162.1 INTRODUCTION**

Familial aggregation of common skeletal deformities is well known. Often this is because the deformity is a component of a simply inherited syndrome, such as the scoliosis that usually occurs in diastrophic dysplasia or the clubfoot that often accompanies spondyloepiphyseal dysplasia congenita. However, even after these syndromes are excluded and only the idiopathic variety of the deformities is considered, familial aggregation still exists. Much interest has been generated in attempting to define the role of genetic and nongenetic factors in these instances. Twin studies, family surveys, and analysis of individual pedigrees have been used, and many potential environmental causes have been investigated. These various approaches have indicated that genetic factors play an important role in the etiology of certain of the deformities, and in several instances, specific modes of inheritance have been identified. Genetic heterogeneity has frequently been uncovered. In certain cases, environmental factors have been incriminated and often their relationship to genetic predisposition defined. For some of them, however, the contribution of genetic factors remains undefined, and in virtually all cases, the precise mechanism by which these factors predispose to the deformities is poorly understood. The goal of this chapter is to examine the current knowledge concerning the inheritance of these common skeletal deformities.

**162.2 IDIOPATHIC SCOLIOSIS**

Scoliosis, curvature of the spine, results from a multitude of causes. Examples of specific causes are poliomyelitis with trunk paralysis, myelomeningocele, neurofibromatosis, and radiation therapy to one side of the trunk (1). Scoliosis is also frequently associated with congenital anomalies, such as hemivertebrae or abnormally segmented vertebral bodies, and with certain of the skeletal dysplasias in which the spine is involved, such as the spondyloepiphyseal dysplasias and spondylometaphyseal dysplasias (2–4). In the vast majority of cases, however, the etiology is obscure, and the term *idiopathic scoliosis* is used.

The incidence of idiopathic scoliosis in the population varies considerably, ranging from 0.2 to 2–8% (1,5). It usually appears and shows the greatest progression during periods of rapid growth, infancy and adolescence. The process may begin during the juvenile period as well but worsens during adolescence. In so-called infantile scoliosis, the curve usually appears during the first year of life, is typically to the left side, often resolves without treatment, and occurs most frequently in boys. It is common in Great Britain, accounting for almost half of all cases of idiopathic scoliosis, but is uncommon in North America. Idiopathic scoliosis of the adolescent variety usually appears during the pubertal growth spurt, is to the right side, and occurs predominantly in girls. Curves developing after the age of 6 years show the characteristics of adolescent scoliosis (6).

Familial aggregation of idiopathic scoliosis has long been recognized. Many forms of inheritance have been postulated, including autosomal dominant, X-linked dominant, and multifactorial inheritance (5–11). Environmental factors have also been proposed to explain this phenomenon (12).

There have been many reports of twins with at least one member of the pair having scoliosis. Fisher and DeGeorge (1967) questioned the validity of those reported before 1967 because of insufficient radiographic studies (13). A total of 24 pairs of monozygous twins and 20 pairs of dizygous twins have been reported since then (6,13–15). The scoliosis detected in one or both twins was almost always the adolescent type. Over 90% of the monozygous twins were concordant for scoliosis, in contrast to 55% concordance for dizygous twins. All of the monozygous twin group were girls, whereas the dizygous twin group contained over one-third boys. Of the dizygotic, unlike-sex group, the girl was most often affected. Thus, the substantially higher rate of concordance for monozygotic compared to dizygotic twins illustrates the importance of genetic factors in the etiology of idiopathic scoliosis. However, the marked preference for girls indicates that sex is a strong determinant as well.

Several surveys have examined the incidence of scoliosis in family members (Table 162-1). They are difficult to compare because different methods and criteria

for diagnosis were used. For example, the diagnosis was made by a questionnaire in the survey of DeGeorge and Fisher (1967), whereas radiography was used by Cowell et al. (1972) and photofluorography by Czeizel et al. (1978) (8,10,12). Moreover, although most of the surveys focused on adolescent scoliosis, some included substantial numbers of only children with infantile scoliosis (6,16). Despite these differences, the surveys showed similar trends. For adolescent scoliosis, the parents and siblings of patients with scoliosis were affected much more frequently than the general population, the incidence ranging from 3 to 35% for parents and from 5 to 36% for siblings. The percentage of affected relatives was much lower in infantile scoliosis: no affected siblings in the study of Connor et al. (1987) and 2.6% of first-degree relatives of infantile scoliosis patients versus 12% in adolescent scoliosis in the survey of Wynne-Davies (1968) (6,16). More recently, Purkiss et al. observed idiopathic scoliosis in 17.3% of offspring of patients with congenital scoliosis (17). When the incidence of scoliosis among second- and third-degree relatives was examined, the surveys showed a dramatic drop-off. Furthermore, girls were consistently affected more often than boys in all categories of relatives, and the frequency of affected relatives was the same for male and female probands (5,10). A recent analysis for adolescent scoliosis among twins from the Danish Twin Registry confirmed the higher concordance for monozygotic twins but suggested that the risk for scoliosis when the other twin has scoliosis is smaller than previously believed (18).

Several other observations were made in these surveys. For instance, plagiocephaly (molding of the head) was common in patients with infantile scoliosis, particularly those with resolving scoliosis (16). It was on the same side as the curve and was transient in almost all cases (6). Mental retardation was found in one-third of patients with progressive infantile scoliosis, where additional malformations were observed in infants with congenital scoliosis (5,6,16). However, except for the high incidence of scoliosis already mentioned, the frequency of the additional anomalies in relatives was the same as in the general population. A substantial elevation of maternal age was found for adolescent scoliosis in three of the surveys (5,6,12), but it was noted to be normal by Filho and Thompson (1971) (7). Finally, Wynne-Davies (1968) observed several instances in which typical infantile and adolescent scoliosis occurred in the same family (6).

The surveys confirm that genetic factors are important in the etiology of idiopathic scoliosis, primarily of the adolescent variety (onset beyond 6 years). Moreover, the incidence figures in first-degree relatives and rapid drop-off in second- and third-degree relatives indicate multifactorial inheritance. According to this model, the highest frequency of scoliosis should be found in the relatives of boys, the least affected sex (19). However, the incidence of affected relatives was found to be

approximately the same for affected boys and girls. The model also predicts that the frequency of affected relatives is related to the severity of the condition in the proband. This was not assessed in most of the surveys because of the many variables that influence the degree of scoliosis, such as age and treatment, although Czeizel et al. (1978) showed a trend in this direction (10). In a few patients, they also observed that the scoliotic curve was slightly greater in offspring of affected fathers than those of affected mothers and greater yet when both parents were affected.

There have also been many families reported in which members in several generations exhibited adolescent scoliosis (8,20–23). Because no instance of male-to-male transmission was seen in 17 families studied in depth, Cowell et al. (1972) proposed X-linked dominant inheritance (8). Riseborough and Wynne-Davies (1973), however, challenged this interpretation because father-to-son transmission had been observed in the families described by the other authors, and it had also been noted in one of their cases (5). Thus, families exhibiting autosomal dominant inheritance of scoliosis do exist.

In summary, genetic factors appear to play a definite role in the causation of idiopathic scoliosis. The observation that infantile and adolescent scoliosis appear within the same families suggests that common genetic factors are involved in both, although they seem to be much more important in the latter. Genetic heterogeneity exists with regard to adolescent scoliosis. In some families, it appears to be transmitted as an autosomal dominant trait. In most, however, it seems to be inherited in a multifactorial manner. The female sex is a strong determinant in converting the genetic predisposition into clinical disease.

The mechanism through which genetic factors operate is unknown. An association between HLA-A19 and scoliosis was reported by Bradford et al. (24). Several investigators have observed abnormalities in collagen and proteoglycan (25–30). In most of the studies, the biochemical alterations were most marked at the region of greatest spinal curvature, making it difficult to determine if they were primary or secondary in nature. Moreover, Carr et al. (1992) showed discordant segregation of adolescent idiopathic scoliosis and the two type I collagen genes (*COL1A1*, *COL1A2*) in four families, making linkage to these loci very unlikely (31). Similarly, Miller et al. (1996) excluded linkage to genes encoding fibrillin 1 (*FBN1*) and elastin as well as *COL1A2* in eleven families displaying apparent autosomal dominant transmission of idiopathic scoliosis (23).

Genome-wide linkage analyses of idiopathic scoliosis have pointed to many locations, including regions on chromosomes 3, 6, 10, 12, 17, 18, 19, and X (32–36). Genome-wide association studies have provided evidence for involvement of the estrogen receptor, matrix metalloproteinase-3 and interleukin-6 in the pathogenesis of idiopathic scoliosis (37–39).

### 162.3 SPONDYLOLISTHESIS

The slippage of a vertebral body forward over the one below it is called spondylolisthesis. It most commonly involves the fifth lumbar vertebra, although the fourth lumbar and occasionally other vertebrae may be affected. Patients are usually symptomatic but may exhibit low back pain, stiffness, or even neurologic symptoms (40). In most instances, the displacement is associated with, and thought to be due to, a defect in the pars interarticularis (posterior inferior process) of the vertebral arch (41). This defect is designated spondylolysis, and five types have been defined: dysplastic (congenital), isthmic, degenerative, traumatic, and pathologic, the most common being the isthmic type (42). Spina bifida occulta often accompanies the dysplastic type (43).

Spondylolysis occurs in 4–8% of the general population over 6 years of age, whereas spondylolisthesis is found approximately half as often (40,44). Familial aggregation of spondylolysis with and without displacement has been observed on several occasions. The dysplastic and isthmic forms of spondylolysis are found in these families. In reviewing spondylolysis, Wynne-Davies and Scott (1979) noted that in most radiographic surveys of family members, about 27% of near relatives were affected (44). In their study, which was restricted to spondylolisthesis of the fifth lumbar vertebra, 19% of relatives had spondylolysis. However, when subdivided according to the type of spondylolysis in the proband, 33% and 15% of relatives of patients with the dysplastic and isthmic forms, respectively, were affected. They also noted that the relatives sometimes had the opposite type of spondylolysis to that found in the index case.

Several individual families have been reported containing multiple affected members (40,41,45,46). Wiltse (1962) postulated autosomal recessive inheritance with incomplete penetrance, but most authors have concluded that autosomal dominant inheritance is more likely (41). In one study, the penetrance was 75% for spondylolysis, and approximately 30% of those patients showed some degree of slippage (40).

The inherited abnormality appears to be a defect in the pars interarticularis of the vertebral arch. It can be either the dysplastic or isthmic type, although the latter is more common (44). Similarly, different vertebral bodies can be affected as evidenced by monozygotic twins who exhibited defects at different levels (41). Radiographically, the defects become evident between the ages of 5 and 7 years (41). The process of fatigue fracture due to repeated stress and trauma rather than an acute traumatic event is thought to be responsible (47). The slippage, if it occurs, usually appears during adolescence, concomitantly with the pubertal growth spurt. The displacement is greater if spina bifida occulta or other vertebral anomalies are present (43). The occurrence of spina bifida seems to be etiologically independent, however, because the incidence of spina bifida and other neural

tube defects is no greater in the patients' relatives than in the general population (44).

Two type IX collagen polymorphisms that introduce tryptophan residues into the triple helical domain of the collagen chain have been linked to an increased risk of lumbar disc disease (48,49). In a study of 107 patients undergoing surgery of the lumbar spine, Matsui et al. (2004) found that a disproportionately high number of patients with a tryptophan polymorphism had spinal stenosis with spondylolisthesis (50).

### 162.4 CONGENITAL DISLOCATION OF THE HIP

Congenital dislocation of the hip (CDH), sometimes referred to as developmental dysplasia of the hip, is characterized by the displacement of the femoral head outside the acetabulum before or slightly after birth. When lesser degrees of displacement occur so that the femoral head articulates with the outer margin of the acetabulum, the term *congenital subluxation* is used. Acetabular dysplasia refers to the development of an abnormally shallow acetabulum without actual displacement (51). CDH is a common birth defect, but the incidence varies considerably throughout the world (Table 162-2), ranging from 0.6 per 1000 whites living in Birmingham, England, to 38 per 1000 North American Indians living in Arizona (52). Although much of the discrepancy is due to different methods of ascertainment or criteria for diagnosis, etc., environmental and genetic factors are thought to be important as well. For example, CDH is more common in infants born in the winter months (53,54). Presumably, the wrapping of the child for warmth keeps the hips in the extended position in which dislocation is more likely. The practice of swaddling an infant to a cradle board with hips extended and adducted for the first few months of life is thought to account for the high incidence of CDH in certain American Indian groups (55). Intrauterine posture is very important as well; both breech presentation and being the first infant born to a mother predispose to CDH (53,54). The female sex is perhaps the major determining factor. CDH occurs approximately six times as often in girls as in boys. It is thought that the production of estrone by the fetal ovary and possibly relaxin by the

**TABLE 162-2 Incidence of CDH**

Location	Incidence (per 1000)
Birmingham, England	0.6
Oslo, Norway	1.0
Salford, England	1.6

Jerusalem, Israel	9.8
Budapest, Hungary	27.5
Arizona, USA (Navajo Indian)	38.0

fetal uterus, both of which increase ligamentous laxity, account for this sex predilection (52,55).

Familial aggregation of CDH has long been recognized. Twin studies have consistently shown a higher concordance rate for monozygotic than for dizygotic twins (Table 162-3). There have been several large surveys in which the incidence of CDH in relatives of probands with CDH has been determined (Table 162-4). In two of the recent studies, the patients were divided into two groups: those having neonatal and those having late onset, depending on whether the diagnosis was made before or after the age of 4 weeks. This was because before 1960 it was not appreciated that CDH could be diagnosed in the neonatal period; most cases were detected when the child began to walk. Thus, the prior studies had dealt primarily with the late-onset type, and it was not known if the patients diagnosed in the neonatal period represented the same or perhaps an etiologically different group. Most recently, an analysis of birth records for infants born Utah yielded relative risk figures of 12.13, 11.85, and 1.74 for first degree relatives, siblings, and first cousins, respectively (56).

TABLE 162-3 Twin Studies in CDH			
Authors	Year	Concordance

Wynne-Davies	1970	1/2	1/3
Czeizel et al.	1975	3/6	0/11

<sup>a</sup>Twins classified as monochorionic.

<sup>b</sup>Twins classified as biovular.

From Czeizel, A., Szentpetery, J., Tusnady, G., Vizkelety, T. Two Family Studies on Congenital Dislocation of the Hip after Early Orthopaedic Screening in Hungary. *J. Med. Genet.* 1975, 12 (2), 125–130.

The incidence of CDH was found to be much higher in relatives of patients with CDH than in the general population in all the surveys. For example, the incidence in siblings ranged from 2.2 to 14%, the highest being in Hungary, where the population incidence is high. In the two studies in which neonatal and late-onset CDH were separated, there were several instances in which both types were observed within the same family (53,54). Moreover, in one pair of dizygotic twins, both types of CDH were found.

The sex preference for girls was observed in affected sibs. For instance, the 5% of affected siblings reported by Record and Edwards (1958) comprised 1% brothers and 10% sisters (57). Similarly, the series of Carter and Wilkinson consisted of 4% brothers and 7% affected sisters (55). In general, the incidence of affected siblings was slightly greater when the proband was male (52,54,58), as would be expected in polygenic inheritance. However, in the two surveys in which the data were subjected to statistical analysis, no significant difference was found (53,54). A dramatic drop-off in the incidence of CDH in second- and third-degree relatives compared with first-degree relatives was observed by Wynne-Davies (1970), Bjerkreim and van der Hagen (1974), and Czeizel et al. (1975) (53,54,58).

The genetic contribution to CDH appears to have two separate components. Based on the observation that the configuration of the acetabulum is determined by a multiple gene system (57), Carter and Wilkinson (1964) postulated that acetabular dysplasia inherited in this fashion interacted with ligamentous laxity, possibly transmitted as an autosomal dominant trait, to predispose an infant to CDH (55). Subsequent studies by Wynne-Davies (1970) (53) and Czeizel et al. (1975) confirmed that “normal” parents of children with CDH have acetabula that measure radiographically as being more shallow than normal (53,59). In the first study, the association was noted only for the late-onset type

of CDH; however, it was observed in both types in the latter investigation. Beals (2003) reported a family with apparent autosomal dominant transmission of acetabular dysplasia (60).

Several studies have demonstrated the occurrence of generalized joint laxity in infants with CDH (53,55,59,61). This was observed especially for boys, and particularly in the neonatal form. Furthermore, these studies showed that it was more common in family members than in the general population; but the mode of inheritance was difficult to determine (i.e. joint laxity is difficult to assess and quantify and tends to decrease with age). Carter and Wilkinson (1964) postulated that this common form of joint laxity was an autosomal dominant trait (55,61). The basis for this speculation appears to have been a few families exhibiting autosomal dominant transmission of generalized joint laxity frequently associated with CDH (62,63). Horton et al. (1980), however, demonstrated that these particular families probably had a separate autosomal dominant trait, which they termed *familial joint instability syndrome* (64). This syndrome can be distinguished from simple joint laxity as seen in CDH by its tendency to present at birth and its association with dislocation of several major joints in addition to the hip. Moreover, the incidence of CDH is approximately equal in boys and girls with this syndrome. Thus it is not clear if the joint laxity in typical CDH is truly an autosomal dominant trait as postulated or may be simply the extreme of normal joint mobility, possibly inherited in a polygenic fashion. In either case, simple familial joint laxity is very common. It occurs in 5% of the normal population and conveys a small but definite risk for CDH (53,61,65).

Thus, CDH appears to be inherited as a multifactorial trait. Acetabular dysplasia transmitted in a polygenic manner and ligamentous laxity inherited in a polygenic or autosomal dominant fashion interact with several factors to bring about CDH. The other factors include female sex (which probably indicates it has a hormonal basis) and others, as yet undefined, that influence the position of the hip before birth and during infancy. Although increased joint laxity may be associated with an early diagnosis and a shallow acetabulum with a later one, the two seem to act additively. Genome-wide studies applied to CDH on a limited basis to date have identified associations of CDH with two developmental regulators of early skeletal development, *TBX4* and *GDF5* (66,67).

## 162.5 CLUBFOOT

Clubfoot is a relatively common congenital anomaly occurring at a rate of approximately 1–3 per 1000 live births (68). It occurs as a component of several syndromes, especially those involving the nervous and connective tissue systems, but also as an isolated developmental anomaly, idiopathic congenital clubfoot. The idiopathic variety shows familial aggregation, but its

inheritance is confusing. Many types of transmission including autosomal recessive, X-linked recessive, autosomal dominant, and multifactorial have been proposed (69,70). Part of the confusion is due to the inclusion of patients with unrecognized syndromes in surveys of idiopathic congenital clubfoot. In addition, many investigators have considered clubfoot as a single entity, when in fact it is composed of three distinct anomalies: talipes equinovarus, talipes calcaneovalgus, and metatarsus varus. The limited number of genetic studies in which this heterogeneity has been appreciated has indicated that the three forms are separate entities (69,71,72).

### 162.5.1 Talipes Equinovarus

Talipes equinovarus is characterized by adduction of the forefoot, inversion of the heel, and plantar flexion of the forefoot and ankle. It is seen in males approximately twice as often as in females, and about 18% of patients exhibit additional minor abnormalities of connective tissues such as joint laxity and hernias (72). In a study of 174 twin pairs, Idelberger (1939) reported the concordance to be 3% in monozygotic twins and 3% in dizygotic twins (73). In a survey of 110 families in 1964, Palmer described 43 families in which at least two members had the deformity (71). Noting instances in which multiple members and three generations of a family were affected, together with the occurrence of male-to-male transmission and an equal ratio of affected males to females, he suggested that autosomal dominant transmission with reduced penetrance was responsible for the deformity at least in certain families. A segregation analysis of data from many of these families and others 10 years later (Palmer et al., 1974) suggested that multifactorial inheritance was more likely (71). However, the incidence in second- and third-degree relatives was higher than expected. This mode of transmission was supported by studies performed by Carter (1965) in which he found that the incidence of talipes equinovarus was 2.1, 0.61, and 0.20% in first-, second-, and third-degree relatives, respectively (19). In addition, a survey of relatives of 340 patients revealed that 2.9% of relatives had talipes equinovarus, whereas talipes calcaneovalgus and metatarsus varus were very infrequent (72). Male relatives of affected females showed the highest rate.

Rebbeck et al. (1993) carried out complex segregation analysis of this deformity in 143 white families from Iowa (74). Their results were most consistent with the hypothesis that talipes equinovarus results from mendelian segregation of a single gene with two alleles plus the effects of other unmeasured factors shared by siblings. Thus, it appears that in most cases, talipes equinovarus is inherited in a manner influenced by both mendelian and non-mendelian factors. The former may predominate in some families. However, for sporadic cases, the recurrence risk to sibs of approximately 3%, as has been used for many years, seems reasonable (71,72).

A microduplication of chromosome 17q23.1q23.2 was recently reported in three families with isolated clubfoot; this region contains the T-box *TBX4* that has been implicated previously in clubfoot (75). There is also evidence for contributions from genes encoding HOX proteins and proteins involved in apoptosis in the etiology of clubfoot deformities (76).

### 162.5.2 Talipes Calcaneovalgus

In talipes calcaneovalgus, there is dorsal flexion of the forefoot and the plantar surface of the foot faces laterally. It is mild, often correcting spontaneously, and it occurs more often in girls (male/female ratio 0.61:1). It is frequently seen in first-born children, suggesting that uterine constraint might be an etiologic factor. Like talipes equinovarus, other minor connective tissue abnormalities occur in approximately 18% of patients, especially congenital dislocation of the hip, which was present in nearly 5% of patients. The incidence of affected sibs is 4.5%, suggesting multifactorial inheritance (72).

### 162.5.3 Metatarsus Varus

Inversion and adduction of the forefoot are found alone in metatarsus varus. It resembles talipes calcaneovalgus in many respects. Often mild, it may go unnoticed. Girls are affected slightly more frequently than boys, and it is observed in approximately 4.5% of sibs. Again, multifactorial inheritance is suggested. It differs, however, in that patients do not exhibit additional minor connective tissue abnormalities, nor does there appear to be any excess of first-born infants (72).

Metatarsus varus is a manifestation of diastrophic dysplasia, which is caused by mutations of the sulfate transporter gene, *DTDST*, also designated solute family 26 (sulfate transporter), member 2 (*SLC26A2*). Since this family of autosomal recessive disorders displays a wide range of severity, it was proposed that “mild” *DTDST* mutations could account for some cases of isolated metatarsus varus. Huber et al. detected homozygosity for the Arg279Trp mutation of *DTDST* in such a case (77). Bonafe et al. found no evidence of such mutations in talipes equinovarus (78).

## 162.6 JUVENILE OSTEOCHONDROSES

The juvenile osteochondroses are a group of disorders in which localized noninflammatory arthropathies result from regional disturbances of skeletal growth (Table 162-5). There is ischemic necrosis of either primary or secondary endochondral ossification centers (79). Most of the abnormalities occur sporadically, but familial forms have been described. Legg–Perthes disease, osteonecrosis of the capital femoral epiphysis, has received the greatest attention. It has been reported as an autosomal dominant trait (80), as a sex-influenced dominant trait

with reduced penetrance (81), and as a multifactorial trait (82). However, these studies were done, or, in the case of Gray et al., data recorded, before the delineation of several simply inherited skeletal dysplasias that exhibit abnormal development of the capital femoral epiphyses. It seems likely that patients with these conditions may have been included in the studies, especially patients with the mild form of multiple epiphyseal dysplasia (Ribbing), an autosomal dominant trait in which involvement may be restricted to the capital femoral epiphyses (3,4). In the recent surveys in which attempts were made to exclude such patients (83–85), the frequency in relatives was found to be very low; approximately 1% of first-degree relatives were affected and the incidence in second- and third-degree relatives approached that of the general population. Moreover, in the three pairs of unselected monozygotic twins reported, all were discordant for Legg–Perthes disease (86). Thus in the vast majority of cases, this condition is not inherited.

Blount disease, a growth disturbance of the medial aspect of the proximal tibial growth plate, occurs in both infancy and adolescence. Pedigrees consistent with autosomal dominant transmission have been reported in the infantile form (87). However, Bathfield and Beighton (1978), in a survey of 231 sibs of 110 patients with the infantile form, found that only 10 were affected (88). They concluded that common environmental factors were largely responsible for the familial aggregation.

Osteochondritis dissecans involving multiple sites, especially the knees, hips, elbows, and ankles, has been

**TABLE 162-5 Juvenile Osteochondroses**

Region Affected	Eponym	Inheritance
Capital femoral epiphysis	Legg–Perthes disease	–
Tibial tubercle	Osgood–Schlatter disease	–
Os calcis	Sever disease	–
Tarsal of navicular bone	Kohler disease	–
Head of second metatarsal	Freiberg disease	–
Vertebral bodies	Scheuermann disease	–
Medial aspect of proximal tibial epiphysis	Blount disease, tibia vara	AD <sup>a</sup>
Subchondral areas of diarthroidal joint (particularly knee, hip, elbow, and ankle)	Osteochondritis dissecans	AD
Capitellum of humerus	Panner disease	–
Patella	Larsen–Johansson disease	–

<sup>a</sup>AD = autosomal dominant.

reported as an autosomal dominant trait in several families (89–91). The condition is characterized by the separation of a small piece of articular cartilage and underlying bone to form a loose body within the joint. Overlap with other of the osteochondroses has been observed. For example, osteochondritis dissecans has been seen in patients with involvement of the tibial tubercle (Osgood–Schlatter disease), spine (Scheuermann disease), the medial aspect of the proximal tibial epiphyses (adolescent Blount disease), patella (Larsen–Johansson syndrome), and the capital femoral epiphyses (Legg–Perthes disease) (90,92). Thus it appears to be a generalized disorder affecting growing epiphyses and may be inherited in some families.

The prevalence of Scheuermann disease was recently studied in a large Danish twin cohort (93). The proband-wise concordance was 0.31 for monozygotic twins compared with 0.13 for dizygotic twins, supporting a genetic component to this condition.

## Biography

**Dr Horton** received AB and MD degrees from the University of Kansas, completed a residency in internal medicine at the University of Kansas School of Medicine and fellowship training in medical genetics at UCLA–Harbor General Hospital, with additional genetics training at the NIH. He has held faculty positions at the University of Kansas School of Medicine, University of Texas Medical School–Houston and Oregon Health and Science University in Portland, where he has also been director of the Shriners Hospital for Children Research Center since 1993. He has a long-standing research interest in skeletal biology with special emphasis on inherited skeletal dysplasias and their molecular pathogenesis. He has published well over 150 articles and book chapters on both the clinical and basic science aspects of these conditions. He is active in many relevant medical and scientific organizations, sits on a number of advisory and review committees and is considered an expert in the field of skeletal dysplasias.

## Hereditary Noninflammatory Arthropathies

Mariko L Ishimori

Division of Rheumatology, Cedar-Sinai Medical Center, Los Angeles, CA, USA

This article is a revision of the previous edition article by Peter H Beighton, volume 3, pp 3865–3871, © 2007, Elsevier Ltd.

### 163.1 INTRODUCTION

Noninflammatory arthropathy is a major manifestation of a number of genetic disorders. There is a great variety of phenotypes, which present a diagnostic challenge in the clinical setting. In some of these conditions this arthropathy is generalized, while in others it predominates in the hip joints, with or without significant involvement of the spine.

Degenerative osteoarthropathy (OA) is the end result of a number of different pathologic processes that culminate in cartilage degeneration, with remodeling and proliferation of new bone. The underlying mechanisms may involve disturbances in skeletal development; minor abnormalities of the cartilage matrix itself, notably, genetic defects of type II collagen; infiltration, as in certain storage disorders; and aseptic necrosis, as in the hemoglobinopathies. In addition, neuropathic joints develop in some hereditary neurologic conditions. Environmental factors may also play a role, and the interaction of primary defects in cartilage and abnormal external forces may be the pathogenetic determinants in some bone dysplasias and hypermobility syndromes. The pathogenetic situation was summed up by Mitchell and Crues (1), who stated “articular disease may result from either an abnormal concentration of force across a joint with normal cartilage matrix or a normal concentration of force across an abnormal joint.”

The general categories of hereditary noninflammatory arthropathy are listed in Table 163-1. Degenerative OA, especially of the weight-bearing joints, is a common complication in a large number of genetic skeletal dysplasias and disorders (2). Many of these conditions have been reviewed elsewhere in this book, but those that have not been covered in the context of OA are outlined in this chapter.

### 163.2 SPONDYLOEPIPHYSEAL DYSPLASIAS

In the 1997 version of the *International Nomenclature and Classification of Osteochondrodysplasias* (3),

several conditions in the spondyloepiphyseal dysplasia (SED) category, in which the underlying defect has been elucidated, were listed as type II collagenopathies. This category was further refined in the 2002 update (4), the 2006 update (5) and most recently, in the 2010 update (6). Other disorders in this group, such as Langer-Saldino dysplasia (achondrogenesis type II), platyspondylic dysplasia, Torrance type, and hypochondrogenesis, present as lethal neonatal dwarfism and do not enter into a discussion of degenerative arthropathy. Equally, Kniest and Stickler syndromes, which are also linked to type II collagen in some affected families (7), and in which degenerative OA occurs together with other significant manifestations, have been fully reviewed in a previous chapter and are not considered further in this section.

SEDs are characterized by predominant involvement of the vertebral bodies and epiphyses of the proximal joints, as well as considerable phenotypic and genetic heterogeneity; in some forms dwarfism with a characteristic shortened trunk is severe, while in others stature approaches normality. Myopia and hearing loss are variable syndromic components. The classical severe form of SED congenita (SEDC) is inherited as an autosomal dominant trait, and is recognizable at birth, but other, milder, autosomal dominant forms may only become evident in late childhood or early adulthood.

Osteoarthropathy of the hip joint, which may be an end result of coxa vara of the hip and/or avascular-necrosis-like changes in the capital femoral epiphysis, is a major cause of handicap in several of these disorders, to the extent that prosthetic joint replacement may be necessary at a comparatively young age. This complication is also of considerable diagnostic significance as it may be the presenting feature of an otherwise mild generalized skeletal dysplasia. Genu valgum and increased laxity of the medial collateral ligament may also be present resulting in pain and degenerative changes in the knee.

Linkage to the type II collagen gene (COL2A1) has been demonstrated in some families with classical SEDC

SED = spondyloepiphyseal dysplasia.

but not in others (8–14,81). This gene is situated on chromosome 12.q13.1–q13.2. In the same way, some of the milder, late-onset forms of autosomal dominant SED have been shown to be linked to type II collagen. For instance, in Namaqualand hip dysplasia, which has been diagnosed in 45 persons in five generations of a South African family (Figures 163-1–163-4), a logarithm of the odds (LOD) score of 7.98 indicates linkage to *COL2A1* (15). More recently, a three-generation family in the United States with mild SEDC was reported with a novel Y-position proline substitution in the triple helical domain (Gly-X-Y) of the pro $\alpha$ 1(II) in *COL2A1* (12). Conversely, a family of British stock with SEDC and generalized OA, living in Kimberly, does not show linkage (LOD 2.26) (16). The determinant gene in this kindred has been reported to be a null mutation in aggrecan (17,18). A mutation in aggrecan was also described in an autosomal recessive form of spondyloepimetaphyseal dysplasia (SEMD), aggrecan type (19). This was a missense mutation affecting the C-type lectin domain of the protein, and was detected in a Mexican family distinguished by severe short stature and a novel group of radiographic findings (19). A similar mutation was recently reported in a Swedish family with autosomal

dominant familial osteochondritis dissecans with mild short stature and early-onset osteoarthritis (20). Characterization of mutations in *COL2A1* has been undertaken, and the Cardiff University Human Gene mutation database (21) lists at least 33 human mutations that have been described. There is great phenotypic variation in SED, making genotype–phenotype correlations more challenging (22) and it is possible that there are hot spots in this gene associated with some forms of mild SED in which OA occurs (23).

Degenerative OA of the hip joint predominates in other dominant mild chondrodysplasias of SED type. In South Africa, Beukes hip dysplasia (Figure 163-5), named after a family of Dutch stock in which 47 persons in six generations are affected, is a disorder of this type (24). This condition has distinctive radiologic stigmata, and there is little doubt concerning its syndromic identity. Beukes hip dysplasia was shown to be not linked to *COL2A1* (25), and the disease-associated gene was subsequently mapped to chromosome 4q35 (26). The osteochondrodysplasias that are of special importance in South Africa have been reviewed by Beighton (27).

In the context of SED, it is noteworthy that in pseudoachondroplasia (PSACH) and some forms of multiple epiphyseal dysplasia (AD-MED), the disease-associated genes are allelic on chromosome 19. The phenotype in these conditions is the result of defective cartilage oligomeric matrix protein (COMP). Considerable intragenic heterogeneity is present, but the phenotypes are fairly consistent (28,29). AD-MED may also result from mutations in matrillin-3 (MAT3) and type IX collagen (30). It has now been shown that an unstable trinucleotide expansion in the *COMP* gene may be the causative mechanism (31). Contraction as well as expansion can occur in the PSACH/MED disorders, with either process producing the disease phenotype. Previously, expansions of this type had largely been recognized in genetic neurologic disorders, and the fact that they can also underlie skeletal disorders has important implications.

### 163.3 FAMILIAL OSTEOARTHROPATHY

The major problems in the elucidation of the genetic determinants of OA are the considerable heterogeneity of the disorder and the great difficulty in precise phenotypic delineation of autonomous entities within this general category. Although OA is common, large families with apparent mendelian transmission of the condition are few and far between.

Primary OA, or degenerative arthropathy, is a very common disorder of middle and old age. More than 80% of all persons over the age of 65 years have radiologic stigmata; of these individuals, about 25% are symptomatic. Risk factors include obesity and trauma, but it is not solely an age-related disorder and there is some evidence for a genetic component (32). The findings of the large-scale Framingham offspring investigation (33), and

**FIGURE 163-1** Namaqualand hip dysplasia in a branch of an affected South African family. The major manifestations are premature degenerative osteoarthropathy of the hip joint.

**FIGURE 163-2** Namaqualand hip dysplasia. Anteroposterior radiographic view of an affected girl, showing early flattening and fragmentation of the femoral capital epiphyses.

**FIGURE 163-3** Namaqualand hip dysplasia. Anteroposterior radiographic view of an affected adult. The hips show advanced osteoarthropathy, with loss of joint space, irregularity, and distortion of the femoral heads, and patchy sclerosis and lucency.

the Baltimore longitudinal study (34) have also indicated that genetic factors are involved. Twin studies have been suggestive of a significant genetic component in OA of the hand and knee (35). It is possible, though unproven, that some “normal polymorphisms” of type II collagen might convey an increased propensity to the development of OA. It is also possible that subchondral bone may be primarily involved in the pathogenesis (36).

The best example of familial OA is probably Heberden’s arthropathy. The influence of heredity in hand OA has been observed and studied in a variety of ways, including the assessment of relative risk in siblings, aggregation in families, and disease concordance in twins. Stecher in 1941 noted a hereditary disposition for

hand OA expression, with a twofold excess of disease in mothers and a threefold excess in sisters of patients with Heberden’s nodes compared with unrelated controls. (37). It is of historical interest that William Heberden (1710–1801), an English physician, gave the following account of the characteristic “nodi digitorum”:

What are those little hard knobs, about the size of a small pea, which are frequently seen upon the fingers, particularly a little below the top, near the joint? They have no connexion with the gout, being found in persons who never had it; they continue for life; and being hardly ever attended with pain, or disposed to become sores, are rather unsightly, than inconvenient, though they must be some little hindrance to the free use of the fingers.

**FIGURE 163-4** Namaqualand hip dysplasia. Lateral radiographic view of the spine of a girl aged 10 years. The vertebral bodies show mild flattening and end-plate irregularity.

The form of generalized OA that is accompanied by Heberden's nodes may represent a sex-influenced or sex-limited autosomal dominant trait (34). It has been suggested that females have a greater genetic liability to OA in general than men (38). A study by Jonsson et al. noted that sisters of patients with interphalangeal joint and first carpometacarpal (CMC1) joint OA have relative risks of 5.0 and 6.9, respectively, to develop OA in the same joint (39). The results of familial aggregation and twin studies provide strong evidence for an inherited predisposition to hand OA. The exact mode of inheritance remains unclear and multiple studies have resulted in reports of association or linkage with a variety of genetic loci (40).

**FIGURE 163-5** Beukes hip dysplasia. Anteroposterior radiographic view of an affected adult. The hips show gross osteoarthritis and a valgus deformity of the femoral necks.

Although this condition is common, the comparatively late onset poses difficulties for family studies and for linkage investigations with respect to the *COL2A1* locus on chromosome 12 (41). An association between an aggrecan polymorphic allele and OA of the fingers has been proposed by Horton et al. (42), and the heritability of OA of the peripheral joints has been discussed by Bijkerk and associates (43). Kalichman et al. (44) undertook a clinical and radiologic investigation of OA of the hands in 1190 persons in 295 nuclear families in a homogenous population of Russian stock. In a sophisticated statistical analysis of their findings, the authors found some evidence of the activity of a major genetic determinant in OA. They could not, however, provide confirmation for a putative gene at 11q12 (45). Associations with *MATN3* mutations have been reported for CMC1 joint involvement in an Icelandic population with familial hand osteoarthritis and also in a separate population with CMC1 OA of the hand with spine OA (46,47). Mutations in *MATN3* have also been reported in AD-MED (48) and matrillin-3 polymorphisms have been associated with spinal disc degeneration and hand osteoarthritis (47). OA at the distal interphalangeal (DIP) and CMC1 joints can occur independently or in the same patient, and it has been suggested that CMC1 OA may need to be treated distinctly from interphalangeal joint OA, as susceptibility linkages may be joint-specific (39,49,50). A genetic linkage study by Hunter et al. found the highest heritabilities at CMC1 and DIP joints as well as the highest LOD scores (51). These investigators also concluded that a joint-specific approach to hand OA genetics may provide greater linkage, as evaluating hand OA as a general entity may decrease the strength of association (51).

The type II collagen gene is a good candidate for the basic defect in primary OA, and linkage was reported more than a decade ago (52,53). This observation would have been of immense importance, in view of the very high frequency of OA in the population as a whole. On further study, however, it emerged that the condition in question was a mild chondrodysplasia with involvement of the vertebrae and epiphyses, and it could thus be categorized in the SED group of disorders (54,55).

The pathogenesis of primary OA is still the subject of intensive investigation. A candidate gene approach to autosomal dominant nonsyndromic OA in a large Dutch family involved 14 collagen or collagen-related candidate genes, of which 10 were excluded (56). Following a radiographic survey in middle-aged persons in Holland, these authors undertook haplotype analysis and identified associations between generalized OA and three polymorphisms in the *COL2A1* gene (57). Loughlin et al. (50) carried out a genomic screen and identified possible OA-related loci on chromosomes 4, 6, and 16. In a subsequent investigation that was focused on chromosome 6, they demonstrated linkage in females but not in males between primary OA of the hip and a locus at 6p12.3–q13, close to the *COL9A1* gene. Further studies of this region using single nucleotide polymorphisms (SNPs) did not support the contention that *COL9A1* was associated with primary OA (58). Possible linkage of OA to a locus on chromosome 2q has been reported (45,59,60). In an investigation in 69 persons in 22 Tasmanian families with digital OA and Heberden's nodes, no linkage with the putative locus on 2q could be demonstrated (61).

It is apparent that there is considerable nonallelic heterogeneity in generalized OA and that the genes that are involved differ in the degree to which they confer susceptibility. In view of the rapid progress in molecular genetics and the importance of OA, however, it seems very likely that determinant genes will be identified in the foreseeable future.

#### 163.4 PRIMARY OSTEOARTHROPATHY OF THE HIP

In the context of primary OA, the question arises as to whether or not OA of the hip joint, in the absence of significant involvement of other joints, is an independent genetic entity. This common disorder in middle age and advancing years is important, as prosthetic joint replacement is often required. Risk factors such as trauma, obesity, and possibly sporting activities apply but are by no means absolute; there is no obvious simple mode of inheritance, but genealogic studies are difficult because of the late onset. Family clustering has been documented (32,62,63), and twin studies have yielded positive results (64). In a comparative study of pelvic radiographs of 135 monozygous and 277 dizygous sets of healthy female

twins, concordance of OA hip was greater in the monozygous twins. The severity of OA was also greater in the monozygous pairs. The authors concluded that genetic factors made a significant contribution to OA of the hip in females (65).

Populations of different genetic stock living in the same environment may provide clues; for instance, in Hawaii, total hip replacement rates are higher in whites than in Asians (66). Similarly, there is a very low prevalence of primary OA of the hip in Asian, black, and East Indian populations (67).

In a large investigation in Iceland, using a database of total hip joint replacements undertaken between 1972 and 1996, family clustering was identified (68). Thereafter, a susceptibility locus on chromosome 16p was identified in a large family (LOD 2.58) (69). At the clinical, radiologic, histologic, and phenotypic levels, this familial OA of the hip was indistinguishable from the idiopathic, nonfamilial OA of the hip (70).

The determinant genes for the  $\alpha_1$  chain of type II collagen and the vitamin D receptor are adjacent loci on 12q. Granchi et al. (71) investigated polymorphic sites in these genes in 143 persons in whom hip joint replacement had been undertaken for primary or secondary OA. The findings were interpreted as providing evidence for a genetic component for the risk of OA in persons with severe hip dysplasia.

Part of the heritability of hip OA may be explained by the hip morphology produced by many of the identified susceptibility genes, which are active during skeletal development (72). On the other hand, as with generalized OA, it is possible that collagen polymorphisms might be involved in the pathogenesis of OA of the hip. The Genetics, Osteoarthritis and Progression (GARP) study identified the deiodinase, iodothyronine, type II (D2) gene (*DIO2*) as a susceptibility gene for hip OA, and found that a mutation in this gene is more likely to increase the vulnerability of cartilage to non-optimal hip morphology instead of causing these shapes (73).

#### 163.5 MSELENI JOINT DISEASE

Mseleni joint disease (MJD) is a remarkable disorder that presents with widespread generalized degenerative OA in late childhood and causes severe crippling handicap in adulthood (74). The condition occurs in high frequency in an isolated area in northern KwaZulu-Natal, South Africa, near the border with Mozambique, and was first described in 1970 (75). Many persons are affected, and the condition has a major socioeconomic impact; the only option for management is prosthetic hip joint replacement. A condition very similar to MJD, Kasin–Beck disease, occurs in the Urov valley of Siberia, parts of China, and North Korea (76). Selenium deficiency, aflatoxins in foodstuffs, and hypoxia (13) have been incriminated in the latter, but despite more than

**FIGURE 163-6** Mseleni joint disease. An affected woman in her home environment. (From Agarwal, S. S.; Phadke, S. R.; Fredlund, V., et al. *Mseleni and Handigodu Familial Osteoarthropathies: Syndromic Identity?* Am. J. Med. Genet. **1997**, 72, 435–439.)

two decades of intensive investigations, no environmental determinants have been identified for MJD. It is of interest that a disorder that resembles MJD, bearing the geographic designation “Handigodu joint disease,” has been documented in several villages in the Shimoga district of Southern India (77).

To date, extensive research has yet to uncover the etiology of MJD. There is no evidence for mendelian inheritance patterns and epigenetic changes in response to the environment have been postulated (78). Type VI collagen has been shown to be overabundant in hip joint cartilage in affected adults undergoing joint replacement, but this finding may represent a secondary phenomenon (79). Among affected persons are dwarfed individuals (Figures 163-6 and 163-7) with the characteristic clinical and radiographic stigmata in severe degree (80). These small persons do not represent a continuum with their affected relatives, in whom stature is essentially normal. Equally, genealogic data do not indicate that they are homozygous for the faulty

**FIGURE 163-7** Mseleni joint disease. Two affected adults with severe stunting of stature. (From Agarwal, S. S.; Phadke, S. R.; Fredlund, V., et al. *Mseleni and Handigodu Familial Osteoarthropathies: Syndromic Identity?* Am. J. Med. Genet. **1997**, 72, 435–439.)

gene. The status of the brachydactylous dwarfs of Mseleni thus remains uncertain. By the end of 2004, there was anecdotal evidence that the incidence of MJD in the Mseleni region was diminishing rapidly. This observation, if substantiated, would be suggestive of the fluctuation of the influence of an unrecognized environmental agent.

## ACKNOWLEDGMENTS

I would like to thank Dr Beighton for writing the earlier editions of this chapter and for the use of his figures. I would like to express my appreciation for the mentorship and guidance of Professor Michael Weisman, Professor Jerome Rotter, and Professor Dan Cohn. I would also like to acknowledge the assistance of Alisa Wilson in the organization of the literature review. This work was supported in part by NIH grant 5K23AR056996 and NIH NCRR CTSI grant UL1RR033176.

### Biography

**Mariko L Ishimori**, MD, is currently Assistant Professor of Medicine at Cedars-Sinai Medical Center in Los Angeles, CA, and Assistant Health Sciences Clinical Professor of Medicine at the David Geffen School of Medicine at UCLA. Dr Ishimori's research interest involves the genetic study of osteoarthritis and lupus nephritis as well as clinical studies in hand osteoarthritis and systemic lupus erythematosus. She has received funding from the General Clinical Research Centers (now Clinical and Translational Science Institute (CTSI)), the American College of Rheumatology, the Arthritis Foundation, and the National Institutes of Health for her research.

## Pathways—Cohesinopathies

Matthew A Deardorff

The Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

Ian D Krantz

Division of Human Molecular Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

### 164.1 INTRODUCTION

The group of diagnoses linked together by their common disruption of the chromosomal cohesion complex, cohesin, or its regulators have been collectively termed “cohesinopathies.” Cornelia de Lange syndrome (CdLS; OMIM #122470, #300590, and #610759), the first disorder found to be caused by alterations in a cohesin regulatory protein, is currently the best recognized and most well studied. While this chapter will discuss a number of the cohesinopathies, the major focus will be on CdLS.

CdLS, also known as Brachmann–de Lange syndrome, is a rare genetically heterogeneous disorder affecting multiple organs and systems during development. Vrolik and Brachmann reported severely affected individuals in 1849 and 1916, respectively (1,2), and de Lange, describing two unrelated individuals, subsequently proposed diagnostic criteria in 1933 (3). CdLS has been estimated to occur in about 1:10,000 to 1:50,000 (4) individuals. However, the actual incidence is likely higher as the clinical presentations are quite variable. With recent molecular diagnostic capabilities, we now realize a higher prevalence of very mildly affected individuals that have been underappreciated and historically were less likely to be diagnosed as CdLS (5). Almost all cases are sporadic, resulting from dominantly acting *de novo* mutations, although recurrence in siblings due to parental (germ line) mosaicism has been reported (6,7), as has direct transmission from mildly affected individuals to their children (8–10). Somatic growth, central nervous system, craniofacial, musculoskeletal, and gastrointestinal systems are the most commonly affected. Additional systemic involvement includes auditory, genitourinary, cardiac, integumentary, hematopoietic, and ophthalmologic. Mutations in three genes, *NIPBL* on chromosome 5p13, *SMC1A* on chromosome Xp11, and *SMC3* on chromosome 10q25, can be identified (collectively) in 70% of individuals with clinically diagnosed CdLS

(8,9,11,12), with *NIPBL* being the major contributor. All of the identified causative genes to date are structural or regulatory components of cohesin.

### 164.2 CLINICAL FEATURES OF CdLS

#### 164.2.1 Growth and Development

Individuals with CdLS have proportionate small stature of prenatal onset, usually identified late in the second trimester. At birth, the measurement parameters are typically below the 10th percentile, and fall to below the 5th percentile by early childhood, although growth parallels standard curves. CdLS-specific growth curves are available (13). In adulthood, average heights and weights are almost universally below the 3rd percentile, and significant microcephaly persists (13). Improved growth parameters may be observed in individuals with *SMC1A* mutations compared to those with *NIPBL* mutations (11). Developmental delay and intellectual disability are typically observed. Speech and language are most significantly affected, while perceptual organization and visual–spatial memory are more preserved. The average IQ ranges from mild to moderate mental retardation; however, both borderline normal and severe mental retardation are commonly reported. Learning continues throughout life without evidence of regression. Early intervention has proven helpful in improving developmental outcomes and should be continued for as long as possible (14). Genotype–phenotype correlations are observed (see below).

#### 164.2.2 Behavior and Neurological Involvement

Almost all individuals with CdLS have some degree of behavioral issues that may be caused or aggravated by

physical complications. Self-injurious behavior, obsessive-compulsive behaviors, attention deficit disorder with or without hyperactivity (ADHD), short attention span, depression, and autistic features have all been consistently reported. Behavioral issues, particularly self-injury and anxiety, usually increase during adolescence. Social and environmental interactions can be achieved to variable degrees (15–18). Seizures are the primary neuropathological manifestation, although only seen in a minority of individuals. No specific electroencephalogram (EEG) pattern has been described and the seizures are generally well managed with standard medical intervention. Sleep disturbances commonly manifest as multiple night awakenings (15). Neuroradiological findings are uncommon but may include enlarged ventricles particularly at the basal cisterns, atrophy of white matter particularly at the frontal lobes, and hypoplasia of the brainstem and cerebellar vermis (19). Gyral structural abnormalities, myelination defects, and neurofibrillary tangles inside neurons have also rarely been reported on autopsy (20,21). Both hypertonia and hypotonia can occur.

Probands consistently have a high pain threshold that may be due in part to a poorly characterized peripheral neuropathy (19).

### 164.2.3 Facial Dysmorphism

The facial features are the most clinically consistent and recognizable finding in CdLS (Figure 164-1). Common features include a short neck, low posterior hairline, hirsute forehead, arched eyebrows, thick and long eyelashes, synophrys, ptosis, low-set ears, flattened midface, short nose, long philtrum, a thin upper lip with down-turned corners, a high palate, widely spaced teeth, and micrognathia. Cleft palate, including submucous clefts, are present in approximately 20% of probands (22,23).

### 164.2.4 Limb Involvement

Typical extremity findings range from small hands and small feet to more severe reduction defects of the upper limbs (Figure 164-2). Disproportional shortening of the

**FIGURE 164-1 Facial Characteristics in Cornelia de Lange Syndrome.** (A) Typically affected 1-year-old male, and (B) 19-year-old male, both with severe truncating mutations in *NIPBL*. Note characteristic facial features (arched eyebrows, synophrys, ptosis, anteverted nares, long philtrum, thin upper lip with down-turned corners and micrognathia) and severe asymmetrical defects of the forearms. (C) More mildly affected 3-year-old boy and (D) 19-year-old girl with missense mutations in *NIPBL*. Note characteristic but more subtle facial features. (E) 7-year-old girl and (F) 5-year-old boy with *SMC1A* mutations and mild facial characteristics.

first metacarpal, proximally placed thumb, brachydactyly, and clinodactyly can be seen in the majority of individuals, and single palmar creases in over half (23). Nearly one third of the probands have upper limb malformations, with severity ranging from various forms of oligodactyly to ulnar deficiency to absent forearm (Figure 164-2). Individuals with CdLS can also have radial head dysplasia with or without radioulnar synostosis resulting in incomplete elbow extension or dislocation (23). The lower extremities are less significantly involved (23) but are generally small, with 2–3 syndactyly of the toes and a short 4th metatarsal being commonly seen. In general, individuals with more significant limb involvement tend to also have more severe cognitive impairment.

### 164.2.5 Visceral Involvement

Almost all organ systems can be involved in CdLS to varying degrees. Gastroesophageal reflux disease (GERD) is nearly universal in CdLS and contributes to feeding problems in infancy and early childhood. Medical treatment is almost always indicated and surgical intervention is often required (17). Ongoing surveillance for GERD throughout the lifetime of an individual with CdLS is important as increased rates of esophageal damage and Barrett's esophagus have been noted consistently (22,24). Pyloric stenosis, diaphragmatic hernia, malrotation, and increased risk for volvulus formation have also been frequently reported (25).

One-quarter to one-third of probands have congenital heart defects, most commonly represented as ventricular or atrial septal defects, although any lesion may be seen (26,27). Renal malformations and dysfunction can be seen as well, commonly represented by vesiculoureteral reflux, pelvic dilatation, and renal dysplasia (28). Major causes of morbidity and mortality in CdLS are gastrointestinal complications including diaphragmatic hernia in infancy, followed by aspiration pneumonia complicated by GERD and volvulus at older ages (23).

### 164.2.6 Additional Systemic Manifestations

**164.2.6.1 Skin.** Hypertrichosis is a common manifestation and is seen mainly on the face, back, and extremities. Cutis marmorata can also be seen in half of the probands (23).

**164.2.6.2 Ophthalmology.** Almost all the probands have peripapillary pigmentation. High myopia, ptosis, nasolacrimal duct obstruction, blepharitis, and mild forms of microcornea are most common. Nystagmus is less commonly seen. Cataract, glaucoma, and other eye malformations are rare (29).

**164.2.6.3 Audiology.** Auditory and vestibular anomalies include both sensorineural and conductive hearing loss, recurrent otitis media, and sinusitis (30,31). Hearing loss may be seen in up to 80% of probands (30,32).

**FIGURE 164-2 Upper Limb Involvement in Cornelia de Lange Syndrome.** (A and B) The more severe reduction defects/oligodactyly typical of the more severe form of CdLS, in this case in two children with severe *NIPBL* mutations. Note typical ulnar side involvement in (A) and characteristic asymmetrical limb involvement in both children. (C) Milder involvement of the hands in a child with a missense mutation in *NIPBL*, manifesting as small hands with 5th finger clinodactyly and short first metacarpal (proximal thumbs). (D) Similar mild hand findings to (C) in a child with an *SMC1A* mutation.

**164.2.6.4 Orthopedic.** Orthopedic manifestations, beyond the upper limb deficiencies described above, include hip dislocation or dysplasia, scoliosis, tight Achilles tendons, and delayed maturation of bone (10,33).

**164.2.6.5 Genitourinary.** In addition to the renal involvement noted above, genitalia are generally hypoplastic with cryptorchidism, micropenis, and hypospadias common in males, and small labia majora in females.

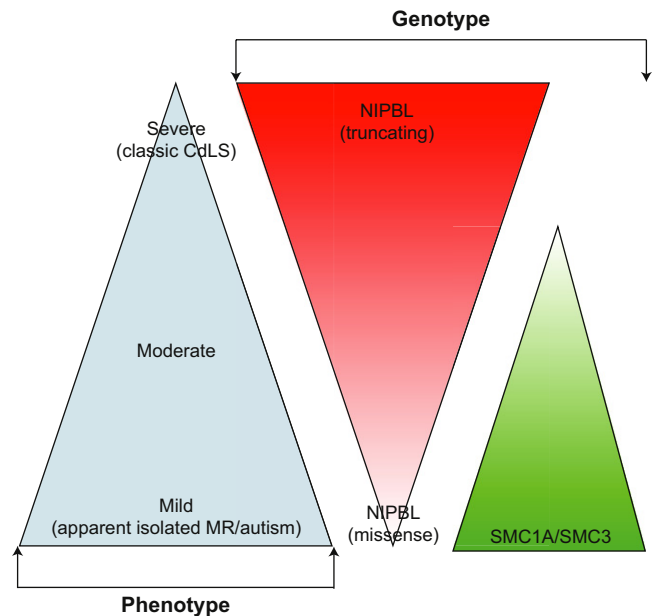

**164.2.6.6 Other.** Normal puberty occurs, although slightly delayed in some (22,23). Fertility is normal amongst less severely affected probands (34). Although less is known about the natural history of CdLS, a few reports describe large cohorts of affected adults. Premature aging has been suggested (22). Other than Barrett's esophagus, as described above, as a result of undiagnosed or poorly managed GERD, there is no obvious increased risk of cancer, although rare cases of liver hemangioendothelioma and Wilms' tumor were reported in autopsies from individuals with features of CdLS (35). Thrombocytopenia has also been consistently reported (36,37).

## 164.3 DIAGNOSIS

Diagnostic criteria and severity scales for CdLS have been proposed (19,38,39), although there is no single set of pathognomonic features of CdLS and diagnosis is based on a constellation of dysmorphism, cognitive, and growth parameters. Identification of a pathogenic mutation in *NIPBL*, *SMC1A*, or *SMC3* is considered diagnostic.

Approximately 60% of CdLS probands have a heterozygous mutation in *NIPBL*. Genotype–phenotype correlations amongst a large cohort of CdLS probands indicate that presumably haploinsufficient *NIPBL* mutations (truncating mutations, splice-site mutations, or frame-shifting indels) often result in a more severe cognitive and structural phenotype than do missense mutations (40). Approximately 5% of probands with a clinical diagnosis of CdLS were found to have missense or small in-frame deletion mutations in *SMC1A* (11,41,42), and one individual was found to have an in-frame 3-bp deletion in the *SMC3* gene (11). Individuals with *SMC1A* and *SMC3* mutations tend to have mild to moderate mental retardation without significant impairments in growth or structural abnormalities of the limb or other organ systems (11). Individuals with *SMC1A* mutations tend to have a more prominent nasal bridge than is typically seen in patients with *NIPBL* mutations (43), and the majority have normal growth parameters at birth and even later in life (Figure 164-1). For most individuals with *SMC1A* mutations, walking and speech are often acquired, and overall this group exhibits a much milder level of cognitive involvement (11). Figure 164-3 summarizes the genotype–phenotype correlations seen in CdLS.

Overall, approximately 65% of CdLS probands with a confident clinical diagnosis have mutations in one of the cohesin-associated genes (*NIPBL*, *SMC1A*, or *SMC3*). Amongst individuals with a more severe, or

**FIGURE 164-3 Genotype–Phenotype Correlations in CdLS.** Left triangle represents distribution of severity seen in CdLS with the classic/severe phenotype being seen in the minority of probands (~30%) and the mild phenotype representing the majority of ascertained probands (some of which have been ascertained as apparent isolated mental retardation and/or autism, who upon referral to genetics were recognized as having subtle features of CdLS). The middle inverted triangle represents the distribution of *NIPBL* mutations identified with the majority of probands, with the classic/severe phenotype having truncating mutations and the majority of probands with a mild phenotype having missense or other frame-preserving mutations. The triangle on the right represents the distribution of mutations seen in *SMC1A* and *SMC3*, with the majority being seen in mildly to moderately affected probands and not seen in the severe/classic form of CdLS.

“classic,” CdLS phenotype, the mutation detection rate is even higher (~80%) and much more likely to involve the *NIPBL* gene. The molecular etiology of the remaining 35% of probands is unknown at this time. Mutations in the regulatory sequences of these three genes may account for a small percentage of cases and are not routinely screened for in clinical testing. Additional cohesin pathway genes are likely to be implicated as causative of CdLS when mutated, and with over 25 known genes implicated in the cohesin complex and its regulation there are many potential candidates.

## 164.4 GENETICS

### 164.4.1 Cohesin Biology

While mitotic chromosomes were first described in the late 1800s (44), it was not until 1985 that the first yeast mutant involved in maintaining the stability of chromosomes through mitosis was described. Termed *SMC1* for stability of mini chromosomes, (45), the gene was subsequently cloned in 1993 (46). With the identification of additional structurally related proteins, “SMC”

**FIGURE 164-4 Cohesinopathies.** Human disorders associated with mutations in cohesin and its accessory proteins. SMC1A, SMC3, RAD21, and either SA1 or SA2 are the four major subunits of cohesin in somatic vertebrate cells. RAD21 crosslinks the head domains of SMC1A and SMC3, in an ATP-dependent manner, whereas RAD21 also binds to the fourth cohesin subunit, SA. NIPBL and MAU-2 form a complex and facilitate cohesin loading and unloading. Sister chromatid cohesion is established during S phase, mediated by sororin and ESCO1/ESCO2, after which PDS5 maintains cohesion through G2 phase. The removal of cohesin from the chromosome arms starts at prophase and is regulated by PLK1, aurora B kinase, condensin I, and WAPL. During the metaphase-to-anaphase transition, the separase inhibitor securin is degraded by APC thereby activating separase, which in turn cleaves centromeric cohesin as well as residual cohesin on the chromosome arms. Recently, ESCO1 and its yeast homolog Eco1 were identified as acetyltransferases required for the acetylation of human SMC3, a necessary step to establish the cohesiveness of chromatin-loaded cohesin during S phase. This acetylation counteracts the effects of WAPL and PDS5, two additional regulatory proteins. SMC3 is subsequently deacetylated during anaphase by yeast Hos1. Cohesin cleavage by separase at the onset of anaphase triggers SMC3 deacetylation, and SMC3 molecules that remain acetylated after mitosis due to Hos1 inactivation are unable to generate cohesion during the subsequent S phase. Human disorders are listed corresponding to their disease-causing genes in the cohesin pathway and at which point in the cell cycle these respective genes are active.

proteins were renamed “structural maintenance of chromosome” proteins (47). The term “cohesins” was coined (48) to clarify the involvement of yeast Smc1, Smc3 and Scc1(Rad21) in a “common cohesion apparatus for all eukaryotic cells in mitosis and meiosis.” Since that time, over 25 proteins have been implicated in cohesin’s

canonical role of controlling appropriate sister chromatid segregation during the mitotic cell cycle.

Cohesin is a dynamic complex regulated at various cell cycle stages by multiple mechanisms (Figure 164-4) (49). The canonical role of cohesin, as first described in yeast, is to control sister chromatid segregation during

both mitosis and meiosis. Four evolutionarily conserved subunits form the core structural component of the cohesin complex, two SMC proteins, SMC1A and SMC3, a kleisin protein RAD21 (also known as MCD1 or SCC1), and STAG1/STAG2 (also known as SA1/SA2). Paralogs SMC1B, REC8, and STAG3, respectively, are cohesin subunits with specialized roles in meiosis (50). Homologs of the cohesin complex and its regulatory genes have been identified in all eukaryotic model systems, including *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Drosophila melanogaster*, *Xenopus laevis*, mouse, and in humans (51).

The protein structures of SMC1A and SMC3 are very similar; each spans 1000–1500 amino acids and contains, at the N- and C-terminal, globular domains each separated by alpha helical structures from a globular “hinge” domain in the middle. The molecule folds around the mid-portion hinge domain to form an antiparallel coiled coil, bringing together the N- and C- domains to form a “head” domain. This cohesin head domain contains three highly conserved motifs: Walker A, Walker B, and a signature motif, that form an ATPase domain (52,53). SMC1A and SMC3 dimerize at the hinge domains to form a V-shaped structure. The N terminus of RAD21 interacts with the head domain of SMC3 and the C terminus interacts with the head domain of SMC1A, with ATP being required for the RAD21 and SMC1 association (54). RAD21 crosslinks the SMC heterodimer, lies in close proximity to the ATPase active sites in cohesin head domains, and binds to the fourth subunit of the cohesin ring structure, STAG1/STAG2 (55). The two prevailing models of cohesin’s mechanism of action in sister chromatid cohesion include the “topological” and “handcuff” models. The “topological” model proposes that the cohesin ring opens to allow sister chromatids to enter the ring and become topologically entrapped when RAD21 relocks the ring (54,56). The “handcuff” model proposes specific interactions of DNA–protein and protein–protein, with one cohesin ring binding one single chromatid after which inter-cohesin complex oligomerization occurs (56–58).

Cohesin has been demonstrated to bind to chromatin. AT-rich cohesin-associated regions (CARs) are distributed at roughly 15-kb intervals at transcriptional convergent sites during G1/S phase in budding yeast (59,60). By contrast, in vertebrates, binding happens during telophase of the preceding cell division. Cohesin also binds at G2/M phase when a double-strand DNA break is created (61). Removal of cohesin from chromosome arms commences in prophase and is completed by early anaphase (Figure 164-4). Although no consensus DNA sequence for cohesin binding has been identified, cohesin binding is enriched at heterochromatin (62) and the chromatin surrounding a DNA double-strand break (DSB) (63).

NIPBL heterodimerizes with hSCC4 (MAU-2) and is required for loading of cohesin onto chromatin in

mitosis, and to all chromosome regions currently under study, such as heterochromatin, CARs, centromeres, and DSBs (63,64). Despite its importance, the mechanism of NIPBL loading of cohesin onto DNA is poorly understood. The NIPBL/MAU-2 complex seems to be involved in all cohesin activities, including SMC ATPase activation, hinge dimerization, chromatin binding, and chromatin remodeling (56). Cells elaborately regulate chromatin binding of cohesin, both temporally and spatially, although most of these mechanisms are unknown at present. This complex regulation enables cohesin to perform diverse biological functions and it is anticipated that mutations in associated proteins will contribute to multiple human diseases, both known and unknown. Cohesin-independent mechanisms of cohesion (e.g. condensin complexes (65), ORCs (origin recognition complexes) (66), centromere complexes (67), and DNA catenation (68)) are also suggested to exist, as complete unpairing of sister chromatids cannot be achieved by knocking down cohesin function alone.

Removal of cohesin from chromosomes is equally complex, with disassociation from the chromosome arms during prophase, while the pericentric cohesin is protected, until the onset of anaphase. In vertebrates, both cohesin subunits STAG2 and RAD21 are substrates of polo-like kinase 1 (Plk1). A functioning Wapl is also required for prophase removal (69–71). Shugoshin/MEIS-322/Sgo1 (72) and sororin (73) protect centromeric cohesins. An evolutionarily conserved protein, Pds5/BimD/Spo76, interacting with Wapl, sororin, and Eco1, is also involved in maintaining pericentric cohesion in prophase (74). Inactivation of cohesion and the complete dissolution of cohesin at the onset of anaphase enable faithful sister chromatid segregation, regulated by securin and separase. Securin binds and inhibits protease activity of separase (Esp1) before anaphase (75). At the beginning of anaphase, securin is degraded by APC (anaphase-promoting complex) and separase is activated (76). The active separase cleaves RAD21 and the cohesin complex is further degraded (75).

Human ESCO1 and its yeast homolog Eco1 are acetyltransferases required for the acetylation of human SMC3 at lysines K105 and K106, a necessary step to establish the cohesiveness of chromatin-loaded cohesin during S-phase (77–79). This acetylation counteracts the effects of WAPL and PDS5, two additional regulatory proteins, which together play roles in dynamically counteracting cohesion (77,78,80–82). SMC3 is subsequently deacetylated during mitosis, and yeast HOS1, a class I histone deacetylase, was identified as the enzyme effecting this role during anaphase (83–85). Cohesin cleavage by separase at the onset of anaphase triggers SMC3 deacetylation, and SMC3 molecules that remain acetylated after mitosis due to Hos1 inactivation are unable to generate cohesion during the subsequent S phase.

### 164.4.2 Cohesin Function and the Etiologies of CdLS and Other Cohesinopathies

With the identification of mutations in cohesin regulatory and structural components that resulted in human developmental disorders (Table 164-1) it was initially speculated that cohesion or cell cycle defects were the cause of the developmental deficits. An early study in a large cohort of CdLS samples suggested that precocious sister chromatid separation (PSCS) was identified in a small percentage of cells in 41% of probands' lymphoblastoid cell lines (LCLs) versus 9% in healthy controls (86). Although, the PSCS noted in these probands was present in a small percentage of any individuals cells and did not involve all sister chromatids. However, subsequent studies have not found obvious cohesion defects in CdLS cells (87). In contrast, in Roberts syndrome (see Section 164.5.1), cells from probands show "heterochromatic repulsion," which was demonstrated by premature sister-chromatid separation primarily at the heterochromatic regions on prophase and metaphase chromosomes (88). It is unclear whether or not the sister chromatid defects seen to varying degrees (or not all) in the cohesinopathies contribute to the phenotypic manifestations of these diagnoses.

Accumulating evidence is suggesting that the non-canonical role of cohesin in regulating gene expression may play an important pathogenic role in CdLS and other cohesinopathies (Figure 164-5). The initial critical evidence for cohesin-mediated gene regulation came from screens that identified the *Drosophila* *Scs2* homolog, *Nipped-B*, to be required for long-range activation of the homeobox genes *cut* and *Ultrabithorax* (*Ubx*) (89,90). The heterozygous *Nipped-B* null alleles reduced *Nipped-B* mRNA only by 25% (a very similar pattern is observed in human (91) and mouse (92) expression studies) with presumed upregulation of the non-mutant allele. Further reduction to 50% wild-type levels by in vivo RNA interference (RNAi) is lethal; however, cohesion defects were not observed. Cohesion defects are seen in the homozygous *Nipped-B* mutant flies; however, these result in

early embryonic lethality (90). Whole-genome mapping of cohesin and Nipped-B chromatin binding sites in *Drosophila* has revealed strong co-localization with cohesin, suggesting that Nipped-B and cohesin remain associated on the chromatin after the loading process (93).

Further support for a role of cohesin in gene regulation has been demonstrated in settings that are independent of sister chromatid cohesion. Homozygous *Drosophila* mutants of *Smc1*, *STAG*, and *Rad21* have shown defective axon pruning of the postmitotic gamma neurons in the developing mushroom body (94,95). As these observations occurred in postmitotic (non-dividing) cells, chromosome segregation and cell cycle regulation are clearly not involved. In zebra fish, the functions of *Rad21* and *Smc3* are needed for proper expression of *runx1* and *runx3* genes in early embryonic development (96).

In addition, a growing body of evidence indicates that cohesin interacts with multiple transcriptional regulatory complexes. Genome-wide chromatin immunoprecipitation experiments in human and mouse cells have identified co-localization of cohesin and CTCF, a zinc-finger protein with enhancer blocking/boundary activities (97–99). Knockdown of either cohesin or CTCF would influence genome-wide gene expression levels, and knockdown of cohesin alone resulted in dysregulated gene expression of CTCF targets (97,98).

Genome-wide gene expression and chromatin immunoprecipitation (ChIP) array studies in lymphoblastoid cell lines have revealed a highly conserved transcriptional profile in CdLS probands that tightly correlates with cohesin binding status (91). In addition, the cohesin complex is necessary for proper function of the transcriptional regulatory mediator complex to maintain expression of pluripotent markers in mouse embryonic stem cells (100). Furthermore, recent work has also demonstrated that the  $\beta$ -globin complex is regulated by cohesin and its chromatin interactions (101). Collectively, data suggest that an important mechanistic action of cohesin complex mutations involves a defect in transcriptional regulation.

TABLE 164-1 Cohesinopathies

Diagnosis	Gene	Chromosome Location	Phenotype Features	Inheritance
Cornelia de Lange syndrome	<i>NIPBL</i>	5p13.1	Severe, moderate and mild CdLS	Autosomal dominant
	<i>SMC1A</i>	Xp11.2	Physically milder CdLS, significant cognitive impairment	X-linked dominant
	<i>SMC3</i>	10q25	Physically milder CdLS, significant cognitive impairment (only one proband identified)	Autosomal dominant
Roberts syndrome/SC phocomelia	<i>ESCO2</i>	8p21.1	No established genotype–phenotype correlation	Autosomal recessive
Warsaw breakage syndrome	<i>DDX11</i>	12p11	Only one proband identified to date	Autosomal recessive
Alpha-thalassemia/mental retardation syndrome, X-linked	<i>ATR-X</i>	Xq13		X-linked recessive

**FIGURE 164-5 Model Depicting Cohesin's Role in Regulation of Gene Expression.** Cohesin and its regulatory proteins have been implicated in regulation of gene expression across multiple species. The disruption of its gene regulatory function is likely the cause of many of the specific developmental features seen in the cohesinopathies. (A) DNA strand with low basal levels of expression (indicated by arrow) across a region where cohesin and CTCF are bound. (B) At specific genomic regions where cohesin and CTCF interact, DNA looping is facilitated and gene expression is altered (in this case upregulated) by the apposition of regulatory elements with promoters.

Currently, 35% of clinically diagnosed CdLS probands have no identifiable mutation in one of the three implicated genes. This suggests other disease-causing genes remain to be discovered or regulatory regions of known genes may be involved. Clear candidates for CdLS or similar disorders would include the other components of the cohesin ring: RAD21 and STAG1/STAG2, or other proteins that interact with or regulate cohesin and modulate its chromatin association dynamics, for example, PDS5A/PDS5B, WAPAL, and sororin.

## 164.5 OTHER DISORDERS OF COHESIN AND SISTER CHROMATID COHESION

### 164.5.1 Roberts/SC Phocomelia Syndrome

Roberts/SC phocomelia syndrome (RBS/SCP; OMIM #268300) is an autosomal recessive genetic disorder

caused by homozygous or compound heterozygous mutations in the *ESCO2* gene (102,103). The clinical features of this syndrome are distinct from CdLS but display systemic overlap (104). The consistent features seen in RBS include pre- and postnatal growth retardation, microcephaly, bilateral cleft lip and palate, symmetric mesomelic limb shortening ("phocomelia") (Figure 164-6), genitourinary abnormalities, and congenital heart defects. The yeast homologous gene *Eco1*/Ctf7 acetyltransferase is required for the establishment and stabilization of sister chromatid cohesion but not for binding of cohesin to chromosomes (105,106). In fission yeast, *Eco1* physically interacts with *Pds5* to counteract its inhibition of cohesion (106). In budding yeast, *Eco1* acetylates *Smc3*'s head domain in a cell-cycle-dependent manner to promote sister chromatid cohesion (77,78). The *Drosophila* *Eco1* ortholog specifically establishes cohesion at centromeres, and not along the chromosome

**FIGURE 164-6 Limb Involvement in Roberts/SC Phocomelia Syndromes.** (A) Shortening of long bones of arms with contractures seen in SC phocomelia. (B, C, and D) More severe involvement of the upper (B) and lower (C and D) extremities of a child with Roberts syndrome. (Photos courtesy of Dr Hugo Vega).

**FIGURE 164-7 Facial Features in ATR-X.** Facial features in a young boy with ATR-X. (A) at 1 year of age, and (B) full face and (C) profile at 8 years of age.

arms (107). Chromosome cohesion defects are seen in cells from RBS/SCP probands demonstrating “heterochromatic repulsion” by premature sister chromatid separation, primarily at the centromeric regions on prophase and metaphase chromosomes (88). A new study has shown that most mutations in *ESCO2* identified in RBS probands result in disruption of the acetyltransferase domain. This results in faulty cohesion and other cellular events in RBS cell lines, indicating the acetyltransferase activity contributes to the development of the major organ systems affected in RBS (108,109). Of interest, studies in zebra fish demonstrated a very different pattern of gene dysregulation in RBS/SCP from that seen in CdLS, with many dysregulated genes involved in cell cycle and apoptotic pathways (110). This suggests that cell proliferation defects and apoptosis may play a significant role in the RBS/SCP phenotype rather than gene dysregulation as suggested in CdLS (110).

### 164.5.2 Disorders Demonstrating Cohesion Defects

Some disorders have associated cohesion defects but the causative proteins have not themselves been directly linked to the cohesin complex or its regulation but clearly interact at some level.

**164.5.2.1 Alpha-Thalassemia/Mental Retardation Syndrome, X-Linked.** Alpha-thalassemia/mental retardation syndrome, X-linked (ATRX; OMIM #301040), is a multisystem disorder characterized by postnatal growth and mental deficiency, microcephaly, dysmorphic craniofacial features (hypertelorism, midface hypoplasia, anteverted nares, and full lips with protruding tongue) (Figure 164-7), lack of speech, seizures, and abnormal genitalia in males. Affected individuals usually have a mild form of hemoglobin H (Hb H) disease. ATRX is caused by mutations in *ATRX* on the X chromosome (111).

*ATRX* encodes a chromatin remodeling enzyme that associates with the chromoshadow domain of HP1 $\alpha$  (as does NIPBL) and preferentially localizes to the pericentromeric heterochromatin in mouse and human cells (112). *ATRX* was suggested to have a role in loading cohesin onto chromatin during S phase and recruiting cohesin to specific chromosome loci (112). Mitotic progression is disrupted in cultured human cells with depleted *ATRX*; defective sister chromatid cohesion and chromosome movement to spindle equator were present at the same time. Similar findings were seen in embryonic mouse brains with no *ATRX* protein (112). The impaired cohesin targeting or transportation due to mutations in *ATRX* may therefore contribute to the clinical phenotypes in *ATRX* syndrome.

**164.5.2.2 Warsaw Breakage Syndrome.** A single male child with severe microcephaly, pre- and postnatal growth retardation, and abnormal skin pigmentation was found to have mitomycin C (MMC)-induced chromosomal breakage in fresh T-lymphocyte cultures, as well as in Epstein-Barr virus (EBV)-immortalized B lymphoblasts (113). Striking centromeric cohesion (“railroading”) and premature chromatid separation (PCS) defects were seen in 50–60% of cells. Reduced levels of the helicase DDX11 were identified and sequencing revealed compound heterozygous mutations. DDX11 is the ortholog of yeast Chl1, and short interfering RNA (siRNA) experiments in human cells point to a role for DDX11 in sister chromatid cohesion.

### Biographies

**Matthew A Deardorff, MD, PhD**, is Assistant Professor of Pediatrics, in the Division of Human Genetics, at The Children's Hospital of Philadelphia and The Perelman School of Medicine at the University of Pennsylvania.

Dr Deardorff trained as a pediatrician and clinical geneticist with a focus in dysmorphology. He has extensive research experience in developmental biology and human developmental disorders. Clinically, Dr Deardorff's pediatric genetics practice focuses on the diagnosis and management of children with rare genetic disorders, with an emphasis on skeletal dysplasias, overgrowth, limb defects, Cornelia de Lange syndrome, and related diagnoses. His research has focused on identifying the molecular etiology of human developmental disorders and understanding the molecular and developmental mechanism by which these identified causative gene changes result in specific phenotypes.

**Ian D Krantz, MD**, is Professor of Pediatrics, in the Division of Human Genetics, at The Children's Hospital of Philadelphia and The Perelman School of Medicine at the University of Pennsylvania.

Dr Krantz trained as a pediatrician and clinical geneticist with a focus in dysmorphology. His clinical interests lie in the diagnosis and management of individuals with multisystem developmental diagnoses. Towards this end, Dr Krantz has established multispecialty clinics to care for individuals with Cornelia de Lange syndrome, Alagille syndrome, Pallister–Killian syndrome, and related developmental diagnoses. His research interests focus on understanding the molecular controls of syndromic human developmental disorders (with a focus on Cornelia de Lange syndrome and Pallister–Killian syndrome) as well as isolated birth defects and sensory deficits (such as congenital heart defects and hearing impairment), and the development of therapeutic strategies for these diagnoses. Dr Krantz is currently the director of the Medical Genetics Training Program at the Children's Hospital of Philadelphia.

Genes and Mechanisms in  
Human Ciliopathies*Dagan Jenkins and Philip L Beales*

Molecular Medicine Unit, UCL Institute of Child Health, London, UK

**GLOSSARY**

- Brachydactyly type A1** – shortening/absence of the middle phalanges in the hands or feet
- Molar tooth sign** – a midline keyhole-shaped defect in the occipital bone dorsal to the foramen magnum commonly found in patients with Joubert syndrome and other ciliopathies
- Polydactyly** – formation of supernumerary digits in either the hands or feet
- Primary ciliary dyskinesia** – a group of disorders defined by primary ultrastructural defects in motile cilia, leading to phenotypes such as brachiectasis, situs inversus and infertility
- Retinitis pigmentosa** – progressive retinal dystrophy caused by degeneration of the photoreceptors in the retinal pigmented epithelium, typically leading to legal blindness in the fourth or fifth decades of life
- Short-rib polydactylies** – several dwarfism syndromes which constitute a subgroup of ciliopathies, characterized by severe shortening of the ribs causing constriction of the thorax and often leading to difficulties with breathing (asphyxiating thoracic dystrophy)
- Situs inversus** – complete mirror image reversal of organ asymmetries. The normal arrangement is known as situs solitus

**165.1 CILIA STRUCTURE AND FUNCTION**

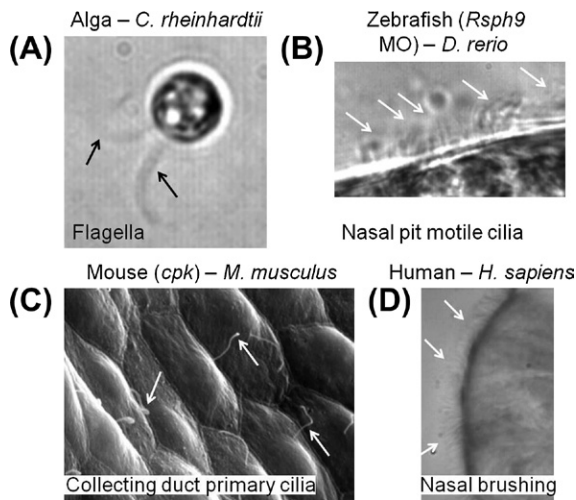

Cilia are microtubular protrusions present on the apical surface of most cells. They consist of a ciliary axoneme, composed of nine outer microtubule doublets (1,2) (Figure 165-1). Some cilia also have a central pair of microtubules, and are therefore known as “9+2” cilia, while others do not have a central pair and are referred to as “9+0” cilia. Classically, “9+2” cilia are motile, exhibiting very regular patterns of beating to generate fluid flow in structures such as the respiratory epithelium (Figure 165-2). The outer doublets are connected by both inner and outer dynein arms that hydrolyze ATP to generate the force necessary for

movement of the cilium (Figure 165-3). Furthermore, radial spoke proteins link the inner and outer doublets in motile cilia, and are essential for proper cilia motility, with mutations in radial spoke proteins causing primary ciliary dyskinesia (PCD). In contrast, “9+0” cilia are generally non-motile, and are referred to as primary cilia to account for the observation that almost all cells within the body will at some point form a single “9+0” cilium. Although generally true, it must also be noted that variations on this grouping into “9+0” and “9+2” cilia have been described (3).

The ciliary axoneme is anchored within the cell by a cytoplasmically located structure known as the basal body, that consists of a mother and a daughter centriole, which are complex microtubule-based structures linked by a fibrous mesh. The centrioles organize a pericentriolar matrix (PCM), which comprises a heterogeneous group of proteins that serve to nucleate microtubules, thereby acting as the major microtubule-organizing center within the cell (4,5). Cilia formation is intimately linked to the cell cycle. The centrosomes are essential for formation of the mitotic spindle, and the centrioles themselves undergo duplication in G2 phase to ensure that both daughter cells have two centrosomes following cell division (6). Cilia only form in quiescent cells in G0 phase, where the centrosomes are recruited to the cell surface to form a basal body and to nucleate the ciliary axoneme. The number of cilia can also vary in different cell types. Whereas most cells will form a single primary cilium at some point, some cells, such as those in the center of the embryonic node, form a single motile cilium. By contrast, some specialized cells, such as respiratory epithelia in the mammalian lung or cells adjacent to mucus-secreting cells on the epidermis of *Xenopus* embryos, can have >50 motile cilia. Whatever the type of cilium, each has its own basal body. Therefore, the formation of many cilia in certain cell types is preceded by massive duplication of centrioles and their subsequent apical docking.

**FIGURE 165-1** The cilium. Schematic representation of a cilium demonstrating the microtubular axoneme surrounded by membrane. Anterograde and retrograde transport via kinesin 2 and dynein 1 are shown on the left and right of the cilium, respectively. Also shown are the ciliary pocket, transition fibers and basal body (see text for details), and as well as vesicles fusing with and budding from the basal membrane.

**FIGURE 165-2** Cilia in diverse epithelia and organisms. (A) Flagella in the free-swimming alga, *Chlamydomonas reinhardtii*. (B) Motile (9+2) cilia in the nasal pit of zebra fish (shown is an embryo injected with a morpholino targeting *Rsp9*; cilia do form in these “morphants,” but cilia motility is perturbed.) (C) Scanning electron microscopy showing primary cilia (9+0) in the collecting duct epithelia of *Cpk* mutant mice (these cilia form normally although signaling is perturbed.) (D) Motile (9+2) cilia of normal human nasal scrapings. (A and B reproduced from Castleman et al. (14), with permission; C reproduced from Jenkins and Winyard 2011, with permission; D—picture courtesy of Amelia Shoemark, Royal Brompton Hospital.)

Cilia/flagella are ancient organelles found in most eukaryotes. Two organisms, which have illuminated the biology of cilia formation are *Chlamydomonas reinhardtii* and the nematode worm, *Caenorhabditis elegans*. *C. reinhardtii* consists of only two cells, each of which

has a single flagellum used for swimming (Figure 165-2; Videos 165-2, 165-3). These flagella have essentially the same structure as mammalian cilia. Indeed, transport of the proteins needed to build the cilium occurs by the same processes as required to build flagella, hence it is termed intraflagellar transport (IFT). The evolutionary conservation of this process is exemplified by the *Ift88* gene, which encodes polaris in mice, and which leads to a complete loss of cilia when inactivated in either mouse, *C. reinhardtii*, or *Ca. elegans* (7–10). Following docking of the basal body and initial nucleation of the ciliary axoneme, so-called “anterograde” movement of various cargo to the tip of the cilium is driven by kinesin-2, a molecular motor that travels toward the “minus” end of microtubules; a second molecular motor known as dynein travels toward the “plus” end of microtubules, toward the cytoplasm, to drive retrograde IFT (11) (Figure 165-1). *Ca. elegans* has specialized ciliary axonemes in certain sensory neurons, and speeds of IFT of around 1  $\mu\text{m/s}$  have been recorded in these cells and also in cultured mammalian cells (12,13). A large and growing family of IFT proteins has been identified, which are essential for cilia formation. IFT proteins are also grouped into those that regulate either anterograde (group B) or retrograde (group A) IFT.

Although the membrane encasing the cilium appears to be contiguous with the rest of the cell membrane, it is now evident that there is regulated movement of both proteins and lipids into the cilium, which means that membrane composition is different in these two areas (15). A critical component of this diffusion barrier at the base of the cilium may be septin 2, a member of the

**FIGURE 165-3** Structure of the ciliary axoneme. (A) Diagram showing the structure and various components of a 9+2 motile cilium in cross-section. (B) Transmission electron microscopy showing a longitudinal section through a motile cilium from a patient with primary ciliary dyskinesia caused by mutation in *RSPH9*. Circle indicates intermittent loss of the central microtubular pair owing to loss of this radial spoke protein. (C) Transverse section through a normal cilium, showing the various components. (D) Patient with *RSPH9* mutation—note absence of central pair. (E) Patient with *RSPH4A* mutation showing abnormal 8+1 structure. (Reproduced from Castleman et al. (2009) (14), with permission.)

guanosine triphosphatase (GTPase) family conserved from yeast (16). Loss of this factor disrupts ciliary membrane protein localization (16,17). Recent evidence has also identified vesicle trafficking proteins with highly specific roles in trafficking various components to cilia. Rab proteins are archetypal vesicle transport proteins, and a screen of 46 Rabs identified only three that were necessary for cilia formation (18). A ciliary necklace (5) and “ciliary pore complex” (19) have also been reported in various species, functioning as barriers through which only selected proteins are allowed passage into the ciliary compartment. The corollary of this is that selective transport will increase the concentration of specific proteins within cilia, which may facilitate targeted interactions. More recently, Molla-Herman et al. described the ciliary pocket, a depression of the plasma membrane in which the primary cilium is rooted (20); the pocket shares many morphologic features with the flagellar pocket of Trypanosomatids, which is a trafficking-specialized membrane domain at the base of the flagellum. The pocket is observed around virtually all primary cilia in mouse retinal pigment epithelial cells but it cannot be absolutely essential for function since it is not universal among kidney cells for example (20).

## 165.2 CLINICAL ASPECTS OF CILIOPATHIES AND CILIOPATHY-LIKE DISORDERS

### 165.2.1 Definition of Ciliopathy

The term “ciliopathy” was first coined in 1984 by Corniliet et al. (21) to describe the varied ultrastructural abnormalities of motile (9+2) cilia observed in the respiratory tracts of children with recurrent respiratory tract infections. This term was subsequently adopted by Badano et al. (3) in its current form, in reference to the varied phenotypes caused by mutations that disrupt cilia or basal body formation. These authors noted a subset of clinical features shared by each of five clinically distinct

syndromes that fall into this category, implicating ciliary dysfunction in their pathogenesis. Since then, the term ciliopathy has variably been used to describe both individual clinical features as well as entire syndromes. The term ciliopathy has also been used rather more speculatively either to describe syndromes featuring defects characteristic of ciliary dysfunction, without evidence that the causative gene is a ciliary protein, or for diseases in which the causative gene has a putative ciliary function even though the clinical features are not characteristic of ciliary dysfunction. To illustrate this point, patients with mutations in *XPNPEP3* develop nephronophthisis, a cardinal ciliopathy (see later), yet this gene encodes a mitochondrial protein that does not appear to function within cilia (22). This more speculative usage has detracted from the original intent of grouping together these disorders.

In this chapter, we will therefore restrict use of the term ciliopathy only to describe phenotypes that can be caused by mutations in several different genes that have been shown to function in cilia, and where there is experimental evidence from model systems that the disease can be caused by ciliary dysfunction (Figure 165-4). While the term ciliopathy is sometimes used more widely to describe whole syndromes, it is likely that some syndromic features are unrelated to ciliary dysfunction, because many ciliary proteins are also likely to have additional functions independent of cilia.

### 165.2.2 An Overview of the Data Summarized in This Chapter

A large repository of information regarding the ciliopathies has accrued from a variety of sources over the last two decades, including human genetics, basic cell biology, proteomics, and biochemical studies. Whereas previous reviews about ciliopathies have variously used databases such as the Online Mendelian Inheritance in Man database or the London Dysmorphology Database to predict ciliopathy disorders on the basis of shared phenotypes, these databases were constructed before the

**FIGURE 165-4** Summary of ciliopathies. Range of ciliopathies are summarized using pictures of Meckel syndrome fetuses to exemplify a severe ciliopathy disorder. (Clinical photographs reproduced from <http://www.humpath.com>, Sainte-Justine Hospital, Montreal, QC, Canada, with permission.)

advent of molecular diagnosis for most disorders, with a primarily clinical nosologic purpose. The predictive capacity of these databases has been reviewed elsewhere (23). Similarly, proteomics databases (in particular the Ciliary Proteome Database) have proven to be a useful guide in identifying new ciliary proteins and new genes mutated in ciliopathies. Nonetheless, this database is likely to include many false-positives, and so proof of ciliary function requires experimental confirmation.

For these reasons, we have limited our analysis of ciliopathies (summarized in Tables 165-1, 165-2, and 165-3) to those for which the causative gene(s) has been identified. We also limit our description of the phenotypes associated with each gene to the actual phenotypes listed for molecularly proven cases in original publications, and we have made every effort to document individual clinical features precisely, and to give some indication about the frequencies with which they occur. For further information, in cases where the same gene is mutated in different syndromes we have also separated the clinical summary for each disorder. We will now describe the broad categories of ciliopathies (Tables 165-1, 165-2), and we will outline the experimental evidence supporting ciliary dysfunction in these disorders. We will then describe the defining clinical aspects of notable ciliopathies.

### 165.2.3 Ciliopathy-Like Disorders

**165.2.3.1 Bardet–Biedl Syndrome.** Bardet–Biedl syndrome (BBS) is diagnosed using a combination of major and minor features. Major criteria are rod–cone

dystrophy, polydactyly, obesity (typically truncal), learning difficulties, hypogenitalism in males, and renal anomalies. A clinical diagnosis of BBS is accepted only if a patient has four major criteria, or three major criteria and two or more secondary criteria. Secondary features are speech disorder, brachydactyly/syndactyly, developmental delay, polydipsia/polyuria, ataxia, diabetes mellitus, abnormal dentition/palatal defects, congenital heart disease, and hepatic fibrosis (109,110). Causative mutations have been identified in 17 different genes in BBS. Many of the encoded proteins are uncharacterized biochemically, and are defined by the structural domains that they contain, such as tetratricopeptide repeats (BBS8) and tripartite motifs (BBS11). A subset of these proteins (BBS1/2/3/4/5/7/8/9 together with BBIP10, PCM-1, and RAB8a) form a protein complex known as the BBSome (discussed later) (111–114). BBS3/ARL6 is a small GTPase involved in vesicle trafficking to the cilium, while BBS6, 10, and 12 are members of the type II chaperonin superfamily that also form a complex (25,26,115).

Several lines of evidence suggest that many BBS proteins function within the basal body. First, comparative analysis of the proteomes of two distantly related ciliated organisms, *Homo sapiens* and *C. reinhardtii*, identified 668 proteins that were shared by these species but that were absent from the unciliated plant *Arabidopsis thaliana*, thereby defining the flagellar apparatus basal body (FABB) proteome. BBS proteins were significantly enriched in the FABB proteome and BBS genes were transcriptionally upregulated following deflagellation of *C. reinhardtii* (31). This analysis, in combination

<i>CRX</i>	Leber congenital amaurosis			(45)	
<i>DYNC2H1</i>	Jeune syndrome	Dynein-heavy-chain protein	<i>Dync2hc1</i> —/— MEFs have abnormal cilia with swollen tip; abnormal cilia in patient chondrocytes	(46,47)	(48)
<i>DYNC2H1</i>	Short-rib polydactyly Type III	Dynein-heavy-chain protein	<i>Dync2hc1</i> —/— MEFs have abnormal cilia with swollen tip; abnormal cilia in patient chondrocytes	(46,47)	(48)
<i>DNAI1</i>	PCD	Dynein-intermediate chain	Ultrastructurally abnormal cilia in patients	(49)	
<i>DNAI2</i>	PCD	Dynein-intermediate chain	Endogenous <i>DNAI2</i> localizes to ciliary axoneme; ultrastructurally abnormal cilia in patients	(50)	
<i>DNAH5</i>	PCD	Dynein-heavy-chain protein		(51)	
<i>DNAH11</i>	PCD	Dynein-heavy-chain protein		(52)	
<i>EVC</i>	Ellis-van Creveld syndrome	Uncharacterized; contains leucine zipper, nuclear localization signals, putative transmembrane domains	Endogenous <i>Evc</i> localizes to the basal body in mouse chondrocytes	(53)	(54,55)
<i>EVC2</i>	Ellis-van Creveld syndrome	Uncharacterized	—	(54)	
<i>EVC2</i>	Weyer acrocardial dysostosis	Uncharacterized	—	(54)	(56)
<i>GLIS2</i>	Nephronophthisis	Kruppel-like zinc finger transcription factor	Endogenous <i>Glis2</i> localizes to the ciliary axoneme in MDCK cells	(57)	
<i>GUC2YD</i>	Leber congenital amaurosis			(58)	
<i>HYLS1</i>	Hydroletharus	Uncharacterized; putative transcription factor with nuclear localization signal	<i>HYSL1</i> is only found in organisms with centrioles, it localizes to centrioles in worms and frogs, it is required for cilia formation in <i>C. elegans</i> ciliated neurons and <i>X. laevis</i> mucociliary epithelium	(59)	(60)
<i>IFT80</i>	Jeune asphyxiating thoracic dystrophy	Intraflagellar transport protein	Endogenous <i>ift80</i> localizes to basal bodies and ciliary axoneme in ATDC5 cells; required for normal ciliogenesis in <i>T. thermophila</i>	(61)	
<i>IFT122</i>	Sensenbrenner syndrome	Intraflagellar transport protein	Reduced cilia length in patient fibroblasts and zebra fish <i>ift122</i> morphants	(62)	
<i>IFT43</i>	Sensenbrenner syndrome	Intraflagellar transport protein	<i>ift88</i> and <i>ift57</i> accumulate at the ciliary tip of patient fibroblasts	(63)	
<i>INPP5E</i>	(MORM—mental retardation, truncal obesity, retinal dystrophy, micropenis)	Inositol phosphatase	<i>Inpp5e</i> —/— mice have reduced number and shorter cilia in cystic renal epithelia, and <i>Inpp5e</i> —/— MEFs have fewer cilia when tyrosine kinase receptor signaling is activated; endogenous <i>Inpp5e</i> localizes to ciliary axonemes in MEFs	(64)	
<i>INPP5E</i>	Joubert syndrome	Inositol phosphatase	<i>Inpp5e</i> —/— mice have reduced number and shorter cilia in cystic renal epithelia, and <i>Inpp5e</i> —/— MEFs have fewer cilia when tyrosine kinase receptor signaling is activated; endogenous <i>Inpp5e</i> localizes to ciliary axonemes in MEFs	(65)	
<i>INPP5E</i>	CORS	Inositol phosphatase	<i>Inpp5e</i> —/— mice have reduced number and shorter cilia in cystic renal epithelia, and <i>Inpp5e</i> —/— MEFs have fewer cilia when tyrosine kinase receptor signaling is activated; endogenous <i>Inpp5e</i> localizes to ciliary axonemes in MEFs	(65)	

INVS	Nephronophthisis type II		Endogenous Invs is present in a punctate pattern along the ciliary axoneme of MDCK cells	(66)
KIF7	ACLS	Kinesin motor protein	Kif7 localizes to the base of cilia in the absence of Shh, and to the tip in presence of Shh; cilia are longer in patient fibroblasts	(67) (68,69)
KIF7	Hydroletharus	Kinesin motor protein	Kif7 localizes to the base of cilia in the absence of Shh, and to the tip in presence of Shh; cilia are longer in patient fibroblasts	(67) (68,69)
KIF7	Joubert syndrome	Kinesin motor protein	Kif7 localizes to the base of cilia in the absence of Shh, and to the tip in presence of Shh; cilia are longer in patient fibroblasts	(70) (68,69)
KTU	PCD			(71)
LCA5/CORF152	Leber congenital amaurosis	Lebercilin; uncharacterized; coiled-coil domain-containing	Endogenous lebercilin localizes to the ciliary axoneme in RPE and IMCD3 cells	(44)
LRA7	Leber congenital amaurosis			(72)
LRRCS0	PCD	Leucine-rich-repeat protein homologous to C reinhardtii outer dynein arm protein 7	Regulates vesicle trafficking to cilia	(73) (74)
MKS3	Joubert syndrome			(75)
NEK1	Short-rib polydactyly Majewski type (Type II)	Kinase domain, nuclear localization and export signals, coiled-coil domains	Endogenous NEK1 localizes to the basal body, and Nek1 is required for ciliogenesis	(76) (77,78)
NEK8	Nephronophthisis	Rcc1-domain-containing; related to never in mitosis A (NIMA)	GFP-NEK8 localizes to centrosomes and cilia; cilia are longer in mice with Nek8 mutations (jck mouse)	(79) (80)
NPHP1	Joubert syndrome			(81)
NPHP4	Nephronophthisis			(82,83)
NPHP5 (IQCB5)	Senior-Løken syndrome	IQ domain protein	Endogenous NPHP5 localized to the ciliary axoneme	(84)
NPHP6 (CEP290)	Joubert syndrome	13 coiled-coil domains, SMC ("structural maintenance of chromosomes" domain), nuclear localization signal, six KID motifs, homology with tropomyosin, ATP/GTP-binding motif (P-loop)	Endogenous CEP290 localizes to the centrosome	(85)
OFD1	Oral-facial-digital syndrome Type 1	Uncharacterized	Localizes to centrosome and interacts with pericentriolar material components	(86,87)
RDH12	Leber congenital amaurosis			(88,89)
RPF65	Leber congenital amaurosis			(90)
RPGR	PCD with RP			(91)
RPGRIP1	Leber congenital amaurosis			(92,93)
RPGRIP1L	CORS	3 N-terminal coiled-coil domains, C-terminal RPGR-interacting domain, two central C2 motifs		(82)
RPGRIP1L	Meckel syndrome	3 N-terminal coiled-coil domains, C-terminal RPGR-interacting domain, two central C2 motifs		(82)

TABLE 165-1 Causative Genes in Ciliopathies and Ciliopathy Disorders—cont'd

Gene ID	Syndrome	Type of Protein Encoded	Function in Cilia Biology	First Discovery (Reference)	Other Refs
<i>RSPH9</i>	PCD	Radial-spoke heavy-chain protein	Connects the inner and outer microtubule doublets to regulate coordinated beating of cilia	(14)	
<i>RSPH4A</i>	PCD	Radial-spoke heavy-chain protein	Connects the inner and outer microtubule doublets to regulate coordinated beating of cilia	(14)	
<i>SDCCAG8</i>	Senior-Løken syndrome	N-terminal globular domain, nuclear localization signal, 8 coiled-coil domains	Endogenous SDCCAG8 is localized adjacent to the centrosome, in centrosomal appendages	(94)	
<i>SDCCAG8</i>	BBS	N-terminal globular domain, nuclear localization signal, 8 coiled-coil domains	Endogenous SDCCAG8 is localized adjacent to the centrosome, in centrosomal appendages	(94)	
<i>TCTN2</i>	Joubert syndrome		Abnormal ciliogenesis in Tctn2 <sup>-/-</sup> mouse embryonic fibroblasts and neural tubes; interacts with MKS1	(28)	
<i>TMEM67</i>	COACH syndrome	Transmembrane protein (predicted)		(95)	
<i>TMEM138</i>	Joubert syndrome	Transmembrane protein (predicted)	Endogenous TMEM138 present in ciliary axoneme as well as cytoplasmic vesicle; knockdown of Tmem138 resulted in fewer cilia	(192)	
<i>TMEM216</i>	Joubert-related syndromes	Transmembrane protein (predicted)	Endogenous TMEM216 present in/adjacent to the basal body/ciliary base; knockdown of Tmem216 resulted in fewer cilia and disrupted apical docking of centrosomes	(96)	
<i>TMEM216</i>	Meckel syndrome	Transmembrane protein (predicted)		(96)	
<i>TMEM237</i>	Joubert syndrome-related disorders	Transmembrane protein (predicted)	Endogenous TMEM237 localizes to the ciliary transition zone and knockdown leads to fewer ciliated cells	(193)	
<i>TTC21B</i>	Nephronophthisis	Intraflagellar transport protein 139	Ttc21b <sup>-/-</sup> mice have abnormal nodal cilia; retrograde IFT is impaired and cilia are shortened, following knockdown of Ttc21b in IMCD3 cells	(97)	(13)
<i>TULP1</i>	Leber congenital amaurosis	Tubby-like protein 1; regulates G-protein-coupled phospholipid signaling		(98)	(99)
<i>TXNDC3</i>	PCD	Thioredoxin enzyme	Ultrastructurally abnormal cilia in patients	(100)	
<i>WDR35</i>	Sensenbrenner syndrome	WDR-repeat-containing and orthologous to IFT121; tubby-like protein 4; binds phosphoinositides	lft88 and lft57 accumulate at the ciliary tip of patient fibroblasts; WDR35 forms part of an IFT-A complex involved in transport of signaling proteins to cilia	(101)	(63,102)
<i>WDR35</i>	Short-rib polydactyly	WDR-repeat-containing and orthologous to IFT121; tubby-like protein 4; binds phosphoinositides	Overexpressed Wdr35 localizes to the basal body, and ciliogenesis is perturbed in Wdr35 <sup>-/-</sup> mice; lft88 and lft57 accumulate at the ciliary tip of patient fibroblasts; WDR35 forms part of an IFT-A complex involved in transport of signaling proteins to cilia	(103)	(63,102)

with genetic linkage data, served to identify mutations in *BBS5*. Secondly, all *Ca. elegans bbs* genes are expressed exclusively in ciliated neurons where they regulate IFT (116,117). Finally, several BBS proteins have also been shown to localize to centrosomes and basal bodies in mammalian cells and tissues (26,30,116,118), and a subset of BBS proteins interact physically to form the so-called BBSome that regulates vesicle transport to cilia (111–114).

### 165.2.3.2 Meckel–Joubert Spectrum Disorders.

Meckel and Joubert syndromes are allelic disorders, and a number of causative genes have been identified. Meckel syndrome is embryonic lethal, whereas Joubert syndrome patients survive past birth. Meckel syndrome is typically caused by complete loss-of-function mutations, whereas Joubert syndrome is often associated with likely hypomorphic mutations. Therefore, in genetic terms, the Meckel–Joubert syndromes represent a spectrum of phenotypic severity. Typically, patients with Joubert syndrome have cerebellar vermis hypoplasia together with a characteristic brain stem malformation on magnetic resonance imaging known as the molar tooth sign (MTS; see Section 165.3.6). Additionally, fetuses with Meckel syndrome have occipital meningoencephalocele, postaxial polydactyly, renal cystic dysplasia, and hepatic disease. Several other disorders overlap clinically with Joubert syndrome, with patients exhibiting the MTS. These include cerebello–oculo–renal syndrome (CORS), with patients also having retinal degeneration and renal cystic disease. A subset of patients also have Joubert syndrome in association with renal disease, and these patients have mutations in *NPHP1* or *NPHP6*, a gene also mutated in patients with nephronophthisis with or without retinal degeneration (the latter known as Senior–Løken syndrome). Collectively, the term “Joubert syndrome-related disorders” has been used to describe this clinical heterogeneity, although the MTS is a pathognomonic feature as shown in Tables 165-1 and 165-2.

### 165.2.3.3 Short-Rib Polydactyilies and Related Disorders.

A number of ciliopathy-like disorders have now been described in which skeletal defects are particularly striking, and patients frequently exhibit very severe defects of the rib cage leading to compression of the thorax. These disorders include the short-rib polydactyilies, Jeune asphyxiating thoracic dystrophy (JATD), and Sensenbrenner and Ellis–van Creveld syndromes, which collectively define a subgroup of ciliopathy disorders. The genes that have currently been found to cause these disorders are *DYNC2H1*, *EVC*, *EVC2*, *IFT43*, *IFT80*, *IFT122*, *NEK1*, and *WDR35* (46,47,53,54,61–63,76,101,104,119); (Tables 165-1 and 165-2). As described below, mouse models deficient for *Dync2h1*, *Evc*, *Ift80*, and *Ift122* have implicated defective hedgehog signaling in skeletal and limb malformations (brachydactyly type-A1 and polydactyly). These patients also exhibit ciliopathies that are not characteristic of defective hedgehog signaling, such as renal

cystic disease, supporting more general roles for these proteins in ciliary function. Indeed, several of these proteins (*IFT122*, *TULP3*, and *WDR35*) have been shown to form a complex, which regulates transport of several G-protein-coupled receptors to cilia in conjunction with *THM1/TTC21B*, which is mutated in patients with nephronophthisis (97). Furthermore, *IFT122* is required to transport *DYNC2H1* into cilia. Interestingly, patients with Sensenbrenner syndrome sometimes also exhibit craniosynostosis. This phenotype is not characteristic of defective hedgehog signaling, although there is growing evidence that elevated hedgehog signaling may contribute to this phenotype in conjunction with alterations in other molecular pathways (120–123), possibly reflecting the regulation of several signaling pathways (including Wnt and platelet-derived growth factor signaling) by the cilium. Finally, it should be noted that the striking rib phenotype in many of these patients is also not typical of defective hedgehog signaling (124). Instead, this phenotype could relate to defects in the sclerotome and dermomyotome, which are somite-derived tissues.

**165.2.3.4 Primary Ciliary Dyskinesia.** PCD is defined by ultrastructural defects in cilia as seen by transmission electron microscopy and altered patterns of cilia beating (Figures 165-2 and 165-3). Ultrastructural defects include absence of various components of the ciliary axoneme. Mutations in several genes (*DNAH5* and 11, and *DNAI1* and 2) lead to loss of outer dynein arms (ODA), whereas only the inner dynein arms (IDAs) are absent in patients with mutations in *CCDC39* (35,49–52). In contrast, *CCDC40* mutations lead to abnormal positioning and/or supernumerary pairs of central microtubules, and *CCDC39* and 40 mutants additionally have abnormal nexin links and abnormal radial spokes (35,36). Therefore, mutations in different components can cause distinct ultrastructural defects. While *DNAH5* and 11 and *DNAI1* and 2 encode dynein chain proteins, which makes sense in light of the ODA defects associated with mutations in these genes, the functions of *CCDC39* and 40 are less clear, although it has been proposed that these genes regulate the assembly of various components of the ciliary axoneme (35,36). *TXNDC3*, another gene mutated in PCD, encodes a thioredoxin enzyme that is expressed as two different mRNA isoforms, the relative levels of which seem to be important for cilia formation (100). Both of the encoded proteins are able to bind microtubules, and so *TXNDC3* may also regulate synthesis of axonemal components. Although *LRRCS0* encodes an uncharacterized protein, it has been speculated that mutations in this gene in PCD affect trafficking from the cytoplasm to cilium (73,74). Finally, mutations have been identified in *RSPH9* and *A4*, which encode radial spoke head proteins that connect the radial stalk and outer microtubules to the central pair, and regulate the bend waveform of cilia as they beat (14). Both *TXNDC3* and *RSPH9/A4* mutant cilia exhibit variable/intermittent

loss of outer dynein arms or central pairs, respectively. Therefore, as well as regulating cilia motility, each component of the ciliary axoneme is also required to maintain structural integrity.

As outlined in Table 165-2, patients with PCD suffer from chronic recurrent respiratory tract infections caused by failed mucociliary clearance. Other associated features include bronchiectasis, sinusitis, and pneumonia. Laterality defects are also common in PCD patients, including situs inversus (known as Kartagener's syndrome), situs solitus, dextrocardia, and polysplenia, which can be explained by the requirement for motile cilia to generate directional fluid flow within the embryonic node (see later). Finally, males are often infertile, owing to impaired sperm flagella function. In summary, PCD represents a distinct class of motile ciliopathies, which is defined by ultrastructural defects in cilia, and

emphasizes the physiologic and developmental importance of cilia motility.

### 165.3 CLINICAL ASPECTS OF CILIOPATHIES

#### 165.3.1 Retinitis Pigmentosa

In the vertebrate retina, the ratio of rods to cones varies among species. The human retina contains about 120 million rod cells and 5 million cone cells but their distribution across the retina is uneven. A third class of photoreceptor cells, the photosensitive ganglion cells, do not contribute to vision directly, but are thought to affect circadian rhythms and the pupillary reflex. Rods are extremely sensitive, and function well in low light levels, being triggered by a very few photons. Contrast

this with cones, which require significantly brighter light to produce a signal.

Photoreceptor cell death is central to the inherited retinal degenerations more commonly termed retinitis pigmentosa (RP). Abnormalities of the photoreceptors (rods and cones) or the retinal pigment epithelium (RPE) of the retina lead to progressive visual loss and may occur in isolation (non-syndromic) or together with additional clinical features (syndromic). Of the non-syndromic forms, RP can be inherited in autosomal dominant, autosomal recessive, or X-linked patterns. More than 170 genes have been associated with RP pathogenesis (source: Retnet database), the most common of which are *RHO*, *RP1*, and *RDS*, accounting for approximately 25–30%, 5–10%, and 5–10% of autosomal dominant RP cases respectively (125,126). In contrast, autosomal recessive RP is rare, with mutations in *RPE65*, *PDE6A*, and *PDE6B*

(phosphodiesterase subunits in the phototransduction cascade) causing 2–5% of cases. *RPGR* (also known as *RP3*) and *RP2* mutations are the most common causes of X-linked RP.

Several gene mutations impact upon the phototransduction cascade, consisting of light-induced conformational change of 11-*cis*-retinal to all-*trans*-retinal, which in turn activates opsins (e.g. rhodopsin). These molecules activate transducin and cGMP-PDE6, with a consequent lowering of intracellular cGMP levels. In one of the best-characterized models of RP, the *rd1* mouse, exon 7 is mutated in the beta subunit of the rod *Pde6* gene, culminating in accumulation of cGMP.

Retinal degeneration is a hallmark of many ciliopathies such as Bardet-Biedl, Alström, and Senior-Løken syndromes in humans and several ciliary gene mouse mutants (e.g. Oak Ridge polydactyly (*Orpk*)). As with forms of Usher syndrome (sensori-neural deafness

het = heterozygous; hom = homozygous.

with RP) and Leber congenital amaurosis, many of the encoded proteins localize to the inner segment or connecting cilium of the photoreceptor where their role is, at least in part, associated with transport of cargo from the inner to outer segments. Disruption to this process leads to inner segment accumulation of opsins and other proteins required for the phototransduction cascade, ultimately triggering cell death.

The clinical presentation of retinal degeneration varies according to the disease and its etiology. For example, in BBS, most children have few signs of eye disease at birth; however, by 6–8 years of age on average, many will have difficulty seeing at low light levels, the so-called night blindness. This will progress to severe daytime loss of visual acuity over the ensuing two decades. BBS-related visual loss is thought to arise from a predominance of rod dysfunction (followed inevitably by cone destruction); hence the night blindness. Contrast this with Alström syndrome (AS), in which most children are born with horizontal pendular nystagmus and have early photophobia owing to disturbance of cones. This leads to a progressive loss of acuity so that it is often difficult to distinguish between AS and BBS later in life.

Despite the ever-increasing number of newly identified RP genes, the pathomechanisms leading to photoreceptor degeneration remain poorly defined. Prior studies suggest that photoreceptor cell loss in RP is driven by apoptosis (126–129) but more recent studies point to alternative mechanisms (130–132).

### 165.3.2 Cystic and Non-Cystic Kidney Disease

Exploitation of the evolutionary conservation of ciliary and flagellar proteins has contributed immeasurably to our understanding of the etiology of ciliopathic disease. The study of model organisms including *C. reinhardtii*, *Ca. elegans*, zebrafish, and mice has been central in the dissection of key phenotypes, renal anomalies chief amongst them. The role for cilia in renal disease came from the initial observation that mutation of the IFT protein IFT88/polaris in the *Tg737* mouse model led to shortened renal tubular cilia (10). Later, proteins encoded by genes mutated in human autosomal dominant polycystic kidney disease, such as polycystin 1 (PC-1) and polycystin 2 (PC-2), localized to the primary cilia membrane in renal epithelial cells (133,134).

Several cilia- or centrosomally localized proteins, when disrupted, cause renal tubular or interstitial disease. Polycystic kidney disease (PKD) is divided into autosomal dominant (ADPKD) and autosomal recessive (ARPKD) types. ADPKD is caused by heterozygous mutations in either *PKD1* (85%) or *PKD2* (15%) whereas ARPKD arises from mutations in *PKHD1* (encodes fibrocystin). ADPKD is the most common ciliopathy, occurring in up to one in 500 persons, and can occur at any age but more commonly manifests in adulthood. By contrast, ARPKD affects around one

in 20,000 persons and onset is always in childhood, and it causes significant mortality in the first months of life.

BBS and AS patients do not invariably have renal disease but can enter renal failure at any point in their life. Around one-third of BBS patients will develop chronic renal disease with tubular cystic degeneration but also with a mixed histologic picture. This may include glomerular cystic disease and tubulointerstitial cell infiltrates with interstitial fibrosis. Many BBS patients also have developmental structural kidney defects with persistence of fetal lobulation, blind ending tubular cysts and calyceal dilation (135). In AS, renal function declines with age, and end-stage renal disease is a common cause of death in AS patients (136).

The autosomal recessive nephronophthisis (NPHP) is the most common cause of inherited end-stage renal failure (ESRF) in children and young adults. NPHP is subdivided clinically, based on the median age of onset of ESRF, into infantile (1 year), juvenile (13 years) and adolescent (19 years). Early clinical signs include polyuria, polydipsia, and secondary anemia. In contrast to ADPKD, NPHP kidneys are either normal or reduced in volume, with much smaller cysts at the corticomedullary junction, tubular basement membrane disruption, periglomerular fibrosis, and tubulointerstitial cell infiltrates with interstitial fibrosis. Twelve NPHP genes have thus far been identified (*NPHP1–11* and *NPHPL1*), accounting for just 30% of cases. Deletion of *NPHP1* was initially discovered in juvenile NPHP (81). The *NPHP2* gene encodes *inversin* and is mutated in infantile NPHP (66) leading to slightly enlarged kidneys that more closely resemble PKD kidneys. *Inversin* mutant (*Inv*) mice develop *situs inversus totalis*, as do a small proportion of *NPHP2* patients.

Joubert and Meckel syndromes are caused by mutations in genes shared with NPHP (e.g. *NPHP1*, *NPHP3*, *NPHP6*, and *NPHP8*). Meckel syndrome fetuses characteristically develop large multicystic kidneys.

Even chondrodysplasia patients with conditions such as short-rib polydactyly, Jeune asphyxiating thoracic dystrophy and cranioectodermal dysplasia who are mutated in key ciliary genes encoding transport proteins (*IFT80*, *IFT122*, *IFT43*, *DYNC2H1*) develop renal cysts.

Finally, oral-facial-digital Type 1 patients (mutated in X-linked *OFD1*) also develop cystic kidney degeneration.

### 165.3.3 Hepatic Disease

Fibrocystic disease of the liver is commonly associated with ciliopathies such as ADPKD, ARPKD, Joubert, Bardet–Biedl, Meckel–Gruber, and oral–facial–digital syndromes. The ductal plate malformation, a developmental abnormality of the portobiliary system, is the basis of the liver disease in ciliopathies that manifest congenital hepatic fibrosis, Caroli syndrome, and polycystic liver disease (137). Hepatocellular function is relatively well preserved in ciliopathy-associated liver diseases.

### 165.3.4 Situs Inversus and Laterality Defects

A broad range of laterality defects are frequently found in many ciliopathies including primary ciliary dyskinesia, BBS (116), OFD1 syndrome, and NPHP (NPHP2). Situs solitus refers to the normal, expected organ configuration, whereas heterotaxy, or situs ambiguus, is the abnormal arrangement of the thoracoabdominal organs resulting in congenital abnormalities. Although Baillie first described situs inversus in 1793, the first link between cilia function and heterotaxy was made in the 1970s by Afzelius when he reported a number of male patients with infertility and the Kartagener's syndrome triad (a form of PCD) (138). Heterotaxy (which can include asplenia or polysplenia) is usually accompanied by multiple congenital abnormalities, the most severe of which are congenital heart malformations (accounting for about 3% of congenital heart defects) such as transposition of the great vessels. The mechanism of nodal signaling is described later in this chapter but many genes (>20) when mutated have now been implicated in the etiology of heterotaxy. Those genes associated with PCD usually encode structural protein members of the motile cilium, such as dynein arms or radial spokes, thus impacting on the function of nodal cilia during early embryogenesis.

### 165.3.5 Polydactyly

Polydactyly is a common manifestation of several human ciliopathies such as BBS, OFD1, JATD, and MKS. It is also present in many mouse models such as *Orpk/polaris/lft88*, *Kif3a* and *Ofd1*. The underlying mechanism associating supernumerary digits with cilia dysfunction was first shown by the Anderson lab in two mouse mutants, *flexo* and *wimble*. These mice displayed up to five additional digits on each limb, which was shown to arise from disruption of hedgehog signaling (described later). They subsequently showed Hh signaling in cells to be dependent on an intact primary cilium, the purpose of which is to regulate Gli activators, which in turn play the major role in limb pattern formation. See Section 165.4.1 for further details (Figures 165-5 and 165-6).

### 165.3.6 Brain Dysgenesis and Malformations

A frequent association with many complex ciliopathies is the presence of structural brain anomalies. In Joubert syndrome where infants present with hypotonia, abnormal jerky eye movements known as oculomotor apraxia, intermittent hyperventilation, and severe cognitive impairment, there are typical posterior fossa lesions such as underdevelopment of the cerebellar vermis, an area of the brain that controls balance and coordination. The

**FIGURE 165-5** Early limb bud development. Scheme showing the early limb bud (~4 weeks in human fetuses), with proximo-distal (what will become shoulder-to-finger-tip) and anteroposterior (little-finger-to-thumb) axes indicated. Shh is secreted from the zone of polarizing activity (ZPA) where it signals to the limb bud mesenchyme and sets up a posterior-to-anterior gradient of positional information. Antagonism between Shh and BMP signaling (by regulating expression of the BMP antagonist Gremlin) modulates expression of Fgf ligand in the apical ectodermal ridge (AER), which in turn signals back to the ZPA and mesenchyme.

MTS is seen on transverse magnetic resonance imaging (MRI) taken at the level of the midbrain in patients with Joubert syndrome. It describes an enlarged and horizontal tubular structure on each side of the midline emerging from the midbrain, reminiscent of a molar tooth, and is caused by a lack of normal decussation of superior cerebellar peduncular fiber tracts. Other posterior fossa defects in Joubert syndrome include Dandy-Walker malformation. Dandy-Walker syndrome is frequently associated with other central nervous system (CNS) disorders including underdevelopment/absence of the corpus callosum, the bundle of axons connecting the two cerebral hemispheres.

Acrocallosal syndrome (ACLS), recently established as a ciliopathy, is characterized by corpus callosum agenesis, polydactyly, multiple dysmorphic features (macrocephaly with prominent forehead and occiput, and hypertelorism) and severe learning difficulties. Mutations in *KIF7* and *GLI3* are causative (67).

Hydroletharus was first distinguished from Meckel syndrome in Finland. There is usually severe polyhydramnios and perinatal lethality. Fetuses have hydrocephalus, micrognathia, and polydactyly. There is hydrocephalus where the corpus callosum and septum pellucidum are absent, often accompanied by cerebellar vermis hypoplasia. A midline keyhole-shaped defect in the occipital bone dorsal to the foramen magnum is characteristic. Unlike Meckel syndrome, cases do not have cystic kidneys or liver, and the CNS anomaly is hydrocephalus rather than posterior encephalocele. The first mutations in Finland where hydroletharus is prevalent were reported in *HYLS1* and more recently, *KIF7* (67).

Subtle changes in the volume of the hippocampus and cerebellum have also been described using structural and

**FIGURE 165-6** Endochondral bone development. Endochondral bones (such as long bones of the limb) form in layers, including the distal growth plates, columnar cells, and hypertrophic zones. These cells progressively differentiate to form a cartilage matrix, which is subsequently invaded by osteoblasts in the perichondrium to form bone. *Ihh* is secreted from the pre-hypertrophic zone, where it signals (a) to columnar cells to allow this population to expand by cell proliferation; (b) to induce *PTHrP* expression in distal cells, which signals to distal columnar cells to delay their differentiation into chondrocytes; and (c) to induce osteoblast differentiation in the perichondrium (these osteoblasts subsequently invade the cartilage matrix to form bone).

functional MRI, in BBS patients (23). Conditional *Kif3a* mouse mutants, as well as mutants of *Ift88* and *Ftm*, all showed defective adult hippocampal neurogenesis, indicating the importance of the primary cilium in transducing sonic hedgehog signal for neuronal development.

## 165.4 MOLECULAR AND DEVELOPMENTAL MECHANISMS IN CILIOPATHIES

### 165.4.1 Role of Cilia in Hedgehog Signaling

Disrupted hedgehog signaling is associated with a characteristic set of birth defects, including agenesis of the corpus callosum, polydactyly, and heart and skeletal malformations, as well as gonadal dysgenesis in boys (124). Hedgehog signaling is currently the clearest example of the mechanisms by which cilia regulate intracellular signal transduction. The basic paradigm of this pathway is conserved from flies to humans, and has been reviewed in detail elsewhere (139). However, there are significant differences between vertebrate and invertebrate hedgehog signaling, and recent evidence has shown that this relates to evolved differences in the role of cilia in this pathway (139–141). Hedgehog signaling proceeds via a series of repressive interactions; three essentially equivalent hedgehog morphogens, sonic (Shh), Indian (Ihh) and desert hedgehog (Dhh), bind predominantly to a single cell-surface receptor, patched 1 (Ptch1). In the absence

of morphogen, Ptch1 represses a second transmembrane protein, smoothened (Smo), which leads to the proteolytic cleavage of the Gli transcription factors, Gli2 and 3, into their transcriptional repressor forms. In contrast, binding of Shh, Ihh, or Dhh to Ptch1 leads to the derepression of Smo, and the accumulation of Gli transcriptional activators.

Although this pathway is highly conserved, both the mechanisms by which Ptch1 represses Smo and those leading to the activation of the Gli transcription factors have remained unclear, and recent evidence suggests that this may involve cilia. In 2007, Rohatgi et al. showed that Ptch1 and Smo exhibit mutually exclusive patterns of ciliary localization—in unstimulated fibroblasts Ptch1 is present within cilia but Smo is not, whereas Smo becomes localized to cilia following application of Shh protein to cells, and Ptch1 concomitantly becomes excluded from cilia (142). Shh was shown to bind directly to Ptch1 at the ciliary membrane, and Smo was constitutively localized to cilia in *Ptch1*<sup>−/−</sup> cells. Further work has suggested that Smo is trafficked directly from the plasma membrane to the ciliary membrane via a process of lateral transport, independent of dynamin-mediated endocytosis (143).

β-arrestins are also essential for trafficking of Smo into cilia following Shh treatment (144). β-arrestins are key regulators of receptor internalization in clathrin-coated vesicles (145), and this work has suggested a model whereby Smo is internalized from the plasma membrane and recycled into the cilium through interaction with the type-II kinesin motor, Kif3a. Smo is

constitutively localized to cilia in cells deficient for the dynein-heavy-chain protein, DYN2CH1 (orthologous to the gene mutated in asphyxiating thoracic dystrophy and short rib polydactyly) (46,47), although these cells fail to elicit a hedgehog response (48,146). Therefore, Smo translocation into cilia is necessary, but not sufficient, for hedgehog signaling. Instead, it seems that IFT of Smo within cilia is essential for active signaling, because a study correlating hedgehog pathway activity with the subcellular localization of Smo in the presence of various agonists/antagonists has suggested the existence of both active and inactive conformations of Smo within the cilium (147). Much less is known about the way in which Smo is transported away from cilia, although Rab23, a key vesicle transport protein involved in early stages of endocytosis, which is mutated in Carpenter syndrome, is one such molecule (120,148–150).

### 165.4.2 Hedgehog Signaling—Limb and Skeletal Malformations

As mentioned in the previous section, some of the ciliopathies are also associated with defective hedgehog signaling, and there is now direct evidence from mouse models of ciliopathy disorders supporting a role for defective hedgehog signaling in pathogenesis. The best evidence for this comes from analysis of skeletal and limb malformations, although there is also evidence that defective hedgehog signaling causes agenesis of the corpus callosum, a cardinal feature of human hedgehog pathway mutations and a ciliopathy (120,124). Mutations in the hedgehog pathway cause a characteristic set of human birth defects, and there is clear phenotypic similarity to ciliopathies (124). Indeed, mutations in *GLI3*, which encodes a transcription factor involved in hedgehog signaling, have occasionally been found to cause oral–facial–digital syndrome Type-1 (151). Furthermore, mutations in *KIF7*, the human ortholog of *Costal 2* that regulates hedgehog signaling in fruit flies, cause ciliopathies as part of ACLS and hydrolethalus (67). Inactivation of each of the hedgehog morphogens gives rise to distinct defects, reflecting their different sites of action. For example, inactivating mutations in *IHH* cause a particular type of dwarfism, acro–capito–femoral dysplasia, owing to its essential role in endochondral ossification. Within the hands, these patients characteristically exhibit absence/shortening of the middle phalanges (brachydactyly type A1). By contrast, *SHH* mutations cause polydactyly, reflecting its indispensable role during early patterning of the limb buds (124,152).

The roles of Shh and Ihh in skeletal and limb development are outlined in Figures 165-5 and 165-6. Briefly, Shh is secreted from the posterior margin of the early limb bud, in a region known as the zone of polarizing activity (ZPA). This establishes a posterior-to-anterior gradient of Shh morphogen, which interacts with other signaling pathways to establish the identities of different

digits. In contrast, Ihh acts somewhat later within the forming endochondral skeleton. Ihh is expressed in the prehypertrophic zone from which it is secreted to activate hedgehog signaling in several cell types—it induces cell proliferation in adjacent chondrocytes, expression of parathyroid-hormone-related protein in distal chondrocytes, and promotes osteoblast differentiation in the perichondrium (152). Owing to these complex roles in endochondral ossification, both gain- and loss-of-function mutations in *IHH* cause shortening of these bones (153–155). Mutations causing either enhanced or reduced Shh signaling within the limb bud also cause polydactyly, suggesting that this is also a default phenotype following loss of positional information.

Consistent with these observations, both skeletal and limb malformations are a common aspect of a variety of ciliopathy disorders (Table 165-2). This is especially striking in the short rib polydactylies, as well as the related Ellis–van Creveld, Jeune, Sensenbrenner, and Weyer’s syndromes. These disorders are characterized by shortening of the long bones, brachydactyly, and severe shortening of the ribs, sometimes leading to asphyxiating thoracic dystrophy, together with polydactyly. To date, causative mutations have been identified in eight genes, *DYNC2H1*, *EVC*, *EVC2*, *IFT80*, *IFT122*, *NEK1*, and *WDR35* (46,47,53,54,61–63,76,101,103,104). *Evc* is expressed in various skeletal structures in the mouse, where the protein localizes to the ciliary base in chondrocytes (55). Mouse mutants of *Evc*, *Ift80*, or *Wdr35* have been analyzed in detail (55,146,156–158), and all three exhibit abnormal skeletal development, including abnormal costochondral junctions within the ribs and shortening of the long bones, associated with abnormal growth plates (55,156).

Several lines of evidence support a role for defective hedgehog signaling in pathogenesis. *Dync2h1* regulates intraflagellar transport, and *Dync2h1*–/– mice exhibit accumulation of material at the ciliary tip (48,159). Although cilia form normally in *Ift80* and *Evc* null-mutant mice, the response to hedgehog morphogen is diminished in fibroblasts derived from all three models (48,55,156,159). Furthermore, overexpression of mutant versions of *EVC2* that are encoded by mutations causing Weyer acroental dysostosis inhibit hedgehog signaling in a dominant-negative manner when overexpressed in wild-type cells (56). Within the tibia of *Evc*–/– mice, reduced expression of hedgehog target genes was also observed in both perichondrium and proliferating chondrocytes (55). Mice lacking either *Tulp3* (the mouse ortholog of *WDR35*) or *Ift122* also exhibit skeletal defects and polydactyly, although in contrast to *Dync2h1*, *Evc*, and *Ift80*, both encode negative regulators of hedgehog signaling (158,160). Emphasizing the generality of disrupted hedgehog signaling in skeletal ciliopathies, knockout in bone of *Ofd1*, the gene mutated in oral–facial–digital syndrome type-1, also causes loss of hedgehog signaling (161).

### 165.4.3 Sensing Fluid Flow and Calcium Signaling—Laterality Defects and Renal Cystic Disease

Both left–right patterning defects and renal cystic disease are key components of ciliopathies. Analysis of these seemingly contrasting phenotypes has implicated primary cilia in the sensation of fluid flow and calcium signaling. This has largely resulted from work on the polycystins PC-1 and PC-2, which are mutated in ADPKD (162,163). Both PC-1 and PC-2 have been shown to localize to the primary cilium of various cell types, where they form a likely receptor–ion channel complex (133).

As well as ADPKD, both mice and zebrafish lacking PC-2 develop laterality defects (164,165). Left–right patterning is initiated by the embryonic node in mice (known as Kupffer’s vesicle in zebrafish), an epithelial invagination in the posterior of the embryo. Two types of cilia decorate the node—motile cilia are present within the node, whereas non-motile primary cilia are located peripherally (166). The motile cilia generate leftward fluid flow, which is thought to bend the primary cilia on the left side of the node (167). Bending of these cilia has been shown to induce calcium influx in the paraxial mesoderm to the left of the node in a polycystin-dependent manner (164,167–169,189). It is important to note that cilia form normally in the absence of PC-2, emphasizing its role in cilia-mediated calcium signaling.

Fluid flow has also been shown to induce calcium influx in cultured Madine–Darby canine kidney collecting duct cells (MDCK), and requires both PC-1 and -2; this calcium influx leads to calcium-induced calcium release from the endoplasmic reticulum by the ryanodine receptor (133). Polycystins also interact with the inositol triphosphate receptor, which also releases calcium from intracellular stores (170,171). High levels of intracellular calcium in renal epithelial cells may lead to the clearance of intracellular cAMP, levels of which are elevated in renal cystic epithelia (172). Fluid flow has recently been suggested to activate mTOR signaling (173), and to regulate gene expression by phosphorylation and nuclear export of the transcriptional co-repressor HDAC5, leading to upregulation of *MEF2C* (174). *Foxj1a*, a master regulator of cilia formation, and its downstream targets are also upregulated following cystic distention of zebrafish pronephric ducts and in *Ift88*<sup>−/−</sup> renal cystic epithelia, leading to increased ciliary beating (175). Therefore, fluid flow and calcium signaling link cilia to the formation of renal cysts. It must be noted that cilia may also regulate other processes that contribute to renal cyst formation, and this has recently been reviewed in detail elsewhere (176).

### 165.4.4 Motile Cilia—Laterality Defects, Infertility, Brachiectasis

Motile cilia are important in a variety of physiologic processes, and disruptions to motile cilia lead to several

characteristic ciliopathies. Cardinal motile ciliopathies include brachiectasis, hydrocephalus, laterality defects, and infertility. Generally, there are three configurations of motile cilia. While some cells, such as those within the embryonic node, carry only a single motile cilium (monociliated), other cell types, such as those lining the respiratory tract, are multiciliated. In contrast, sperm possess flagella, which are specialized motile cilia that propel them into the female reproductive tract. Interestingly, whereas most motile cilia have a 9+2 configuration, motile cilia within the node are unique in having a 9+0 structure.

Clearance of mucus in the respiratory tract is necessary to prevent infection (177), and ultrastructurally abnormal cilia have been reported in children with recurrent respiratory tract infections (21). Furthermore, motile cilia on ependymal cells lining the ventricles of the brain are necessary for cerebrospinal fluid flow. A crucial determinant of directed ciliary beating is the orientation of cilia. Within the multiciliated epithelium of the respiratory tract, all cilia on the epithelial surface point in the same direction, which allows the coordinated movement of the cilia in a wave-like motion to move mucus in one direction (Video 165-2). At the tissue level, correct orientation is achieved by planar cell polarity (PCP)—that is, all cells have intrinsic polarity within the plane of the epithelium. PCP is achieved by specific PCP-related proteins that are distributed asymmetrically within each cell, which is established by extracellular cues such as Wnt ligands (178).

At the cellular level, the asymmetric orientation of cilia results from the positioning of basal bodies (178,179). Similar mechanisms regulate the positioning of motile monocilia within the embryonic node, which point to the left and posterior of the node so that the different forces generated by the up- and down-strokes collectively generate leftward fluid flow (180,181). In the previous section, the importance of cilia in activating calcium signaling specifically on the left side of the node was discussed. In contrast, the importance of leftward fluid flow within the node was elegantly demonstrated by experiments using a flow culture system to reverse flow to the right hand side—this resulted in signal transduction to the right of the node (167). This has also been confirmed by the characterization of many mutants that perturb motile cilia within the node, leading to randomization of signaling lateral to the node and randomized organ laterality.

Although generally identical in structure, cilia and flagella exhibit very different patterns of movement. While cilia generally exhibit back-and-forth bending, flagella generate a propeller-like circular motion, allowing them to propel individual cells through liquid. The motility of both flagella and conventional 9+2 motile cilia relies on the integrated structure of the ciliary axoneme. In particular, the inner and outer dynein arms that interconnect the outer microtubule doublets generate the shear force

required to bend the cilium, and this is regulated by the nexin link (Figure 165-3). The radial spokes are crucial to translate this movement to the central microtubules. In particular, this connection translates the force generated by the dynein arms into regular and coordinated movement. It is likely that regulatory/accessory proteins determine the exact pattern of movement that different cilia display. Defects in these coordinated movements lead to the motile ciliopathies described, including male infertility owing to impaired movement of sperm. Interestingly, fathers who are heterozygous for mutations in PCD genes do not display reduced fertility. This is an important point, not only for genetic counseling, but because if this was the case, one might expect the mutation never to be passed on to children owing to selection of sperm carrying the wild-type allele. The reason this does not occur is likely to be because diploid spermatogonial stem cells provide long-lived mRNA necessary for the subsequent development and function of haploid sperm, and because sperm themselves seem capable of sharing these transcripts subsequently (182).

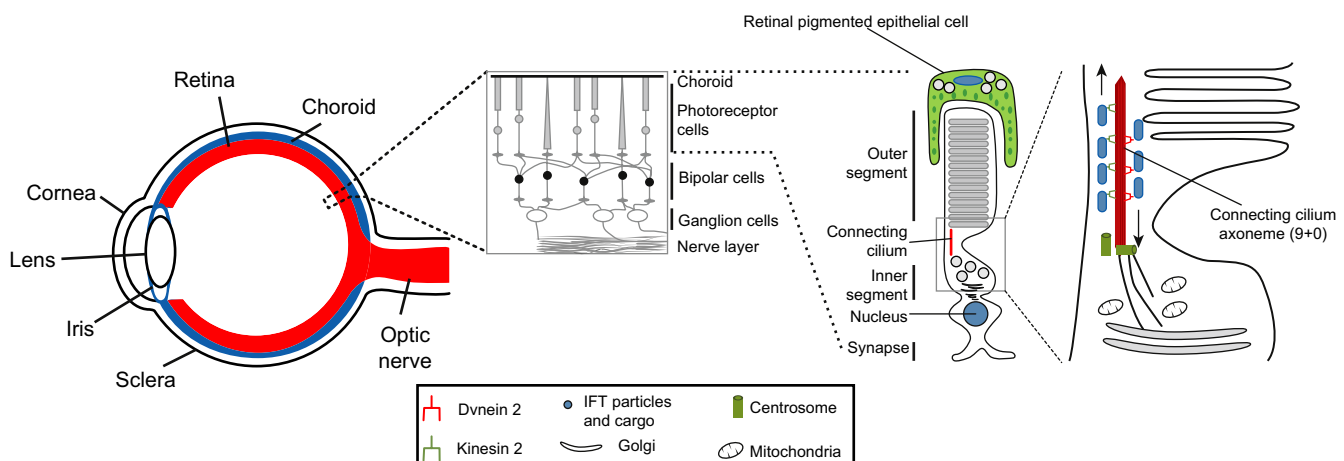

### 165.4.5 Specialized Sensory Cilia—Retinal Degeneration and Deafness

Photoreceptor cells in the retina are one example of specialized sensory cilia. They consist of a synaptic terminus, a nucleus, and inner and outer segments (Figure 165-7). While the membrane stacks that contain all of the photosensitive pigment are present in the outer segment, all of the cellular machinery for biosynthesis is present in the inner segment. All of the cellular material that makes up the outer segment must therefore be transported to that location, and this is achieved by dynein- and kinesin-mediated transport along the connecting cilium that connects the two segments. Likewise, the absence of biosynthetic machinery within more conventional cilia

means that proteins and lipids must be transported to cilia by both vesicle transport and IFT. The connecting cilium of photoreceptors consists of microtubule doublets arranged in a 9+0 configuration, and is essentially identical to the ciliary axoneme of primary cilia.

*RPGR* is mutated in approximately 20% of patients with X-linked retinitis pigmentosa (183), a severe form of retinal degeneration similar to that seen in many patients with Bardet–Biedl and Senior–Løken/nephronophthisis syndromes. *RPGR* localizes to the connecting cilium and interacts with several IFT proteins, and probably regulates transport along the connecting cilium (184). *RPGR*-interacting protein 1 (*RPGRIP1*) also localizes to the connecting cilium, and interacts with a very similar protein encoded by *RGRIP1L*, which is mutated in both *CORS*, which is clinically similar to Joubert syndrome and Meckel syndromes, sometimes in combination with *RP*. *RPGRIP1L* also interacts with nephroretinin, which is encoded by the *NPHP4* gene that is also mutated in *RP* and nephronophthisis (82,83). Therefore, retinal degeneration can be caused by defective transport along the specialized connecting cilium of photoreceptor cells.

Specialized ciliary axonemes, so-called kinocilia, are also a striking feature of sensory hair cells within the inner ear of mammals. Each kinocilium (one per cell) is associated with many stereocilia, actin filament bundles encased by membrane. Collectively, kinocilia and stereocilia form a chevron-shaped bundle of cytoskeletal components that sense auditory vibrations (185) (Figure 165-8). Defects in their formation can cause sensorineural hearing loss and balance disturbance. As previously discussed, motile cilia are often orientated asymmetrically within the plane of an epithelium to generate fluid flow. This PCP is also apparent in the organ of corti, where the hair cells reside, and PCP proteins are also required for the proper orientation of kinocilia and

**FIGURE 165-7** Photoreceptors in the eye represent specialized cilia. From left to right: schematic showing the overall structure of the eye; a section of the retina (boxed region) expanded to show the different cell layers, including photoreceptor cells (rods and cones); expanded photoreceptor cell (together with associated retinal pigment epithelium cell) showing inner and outer segments adjoined by the connecting cilium; expanded view of the connecting cilium showing dynein- and kinesin-mediated anterograde and retrograde transport.

**FIGURE 165-8** Specialized kinocilia on hair cells in the inner ear, and planar cell polarity. Scanning electron micrographs of the 6-week-old mouse cochlea showing that each hair cell possesses stereociliary actin bundles arranged in a chevron shape. Note that the single kinocilium that was present at the apex of these stereociliary bundles has degenerated by this stage. In the wild-type, the orientation of these actin bundles is organized within the plane of the epithelium, whereas several are abnormally rotated in *Bbs6*<sup>-/-</sup> mutants (white arrows).

stereocilia. This is achieved following migration of the basal body to the abneural side of each hair cell, where it nucleates microtubules. BBS proteins are required to maintain the correct planar cell polarity of hair cells in mice, in conjunction with PCP proteins (186,187).

Usher syndrome is the most common cause of coexisting hereditary blindness and deafness. Several Usher syndrome proteins maintain connections between stereocilia, and also localize to the connecting cilium of photoreceptor cells. Some patients with this condition also exhibit sinusitis and bronchiectasis, further suggesting a role in mucociliary clearance and thus a wider role in ciliary function. Therefore, it has been suggested that some subtypes of Usher syndrome may be considered ciliopathies. On the other hand, mouse models of Usher syndrome do not exhibit altered planar polarity of hair cells, but instead have fewer and disorganized stereocilia, and so Usher proteins may function independently of other ciliopathy proteins.

### 165.5 DIRECT INTERACTIONS BETWEEN CILIOPATHY PROTEINS AND EVIDENCE FOR COMPLEX INHERITANCE IN A SUBSET OF FAMILIES

As listed in Table 165-1, causative mutations in at least 70+ genes have been identified in ciliopathy disorders. All ciliopathy disorders follow an autosomal recessive pattern of inheritance, with the single exceptions of oral-facial-digital syndrome Type I, which is X-linked recessive, and Weyer acroental dysplasia, which can be caused by heterozygous dominant-negative mutations in the Ellis-van Creveld syndrome gene, *EVC2* (53,86,87,104). There is also extensive genetic heterogeneity, with as many as 17 genes mutated in BBS, and 10 genes causing Leber congenital amaurosis, for example. Given that this large number of

genes are associated with overlapping phenotypes, it is perhaps not surprising that many of the encoded proteins interact, and some form multiprotein complexes. One example is the so-called “BBSome,” formed by a subset of BBS proteins, that has been shown to regulate vesicle trafficking to the basal body in conjunction with small GTPases, Arl6 (encoded by *BBS3*) and Rab8a (111–114). Another complex that traffics G-protein-coupled receptors into cilia involves associations between WDR35 and IFT122 (both of which are mutated in Sensenbrenner syndrome/short rib polydactyly) (101,103), as well as THM1/TTC21B (mutated in nephronophthisis) (97), TULP3, WDR19, and IFT140 (102). Interestingly, several of these proteins have been shown to negatively regulate hedgehog signaling, consistent with skeletal defects in Sensenbrenner syndrome and suggesting that formation of this complex is functionally relevant in pathogenesis (13,157,158,160,188). *INV/NPHP2* and *LCA5*, which are mutated in nephronophthisis and Leber congenital amaurosis, respectively, are further examples of proteins that have multiple interacting partners (44,66) and references therein. Therefore, the exclusive recessive inheritance and extensive genetic heterogeneity is likely to reflect complex interactions between networks of ciliopathy genes, involving many specific protein–protein interactions.

Molecular genetic findings also support functional interactions between ciliopathy proteins, because several examples of allelism between distinct ciliopathy disorders have been described. For example, several genes mutated in nephronophthisis, including *SDC-CAG8* (94), also segregate pathogenic mutations in BBS families. Meckel–Grüber and Joubert/Joubert-related syndromes have also been shown to be allelic, with mutations in *CC2D2A*, *CEP290*, *INPP5E*, *MKS3*, *RPGRIP1L*, *TMEM67*, or *TMEM216* causing both conditions (37,38,41–43,64,65,75,82,95,96). Indeed, identical missense mutations in *TMEM216* can cause either condition, and both phenotypes were found to coexist in at least one sibship (96). There is also a clear genotype–phenotype correlation—whereas homozygous/compound heterozygous nonsense or frameshift mutations cause the more severe embryonic-lethal Meckel–Grüber syndrome, patients with Joubert syndrome caused by mutations in *CC2D2A*, *INPP5E*, *MKS3*, or *RPGRIP1L* always carry at least one missense mutation, which are likely to represent hypomorphic alleles (37,38,43,64,65,82,95,96). A similar scenario is also found in patients with mutations in *DYNC2H1*, *IFT80*, *IFT122*, or *WDR35*, causing either short rib polydactyly or Sensenbrenner syndrome, who also always carry at least one missense/point mutation, suggesting that homozygous/compound heterozygous nonsense or frameshift muta-

tions would be lethal or cause a more severe phenotype (46,47,61,62,101,103).

These observations clearly show that a spectrum of clinical severity exists in ciliopathies, dependent on the mutational load. The existence of large complexes of ciliopathy proteins further raises the possibility that mutations in multiple ciliopathy genes may participate in complex inheritance. The first evidence supporting this possibility came from examples of possible triallelic inheritance in BBS, whereby three mutant alleles in two genes are required to cause disease (105,107). Resequencing of *BBS* genes in large numbers of patients identified a small number of families with mutations in more than one *BBS* gene, and in some families, patients with three mutant alleles had a more severe clinical presentation than relatives with only two mutations in a single gene. Furthermore, in other families individuals were very occasionally described who carried two known pathogenic mutations in a single *BBS* gene, but who were clinically normal (a notable example is the M390R mutation in *BBS1*, the most common mutation in BBS) (24,29,106). Since these initial studies, families segregating three mutations in two genes have been described for other pairs of ciliopathy genes in nephronophthisis, Leber congenital amaurosis, and Joubert, Meckel, and Senior-Løken syndromes also (listed in Table 165-3). It has also been suggested that some of these “third” alleles may act as tissue-specific modifiers. For example, the R830W polymorphism in the *AHI1* gene was found more commonly in, and was over-transmitted to, patients who had two mutant alleles in *NPHP* genes and presented with nephronophthisis and retinitis pigmentosa, in comparison to patients with nephronophthisis alone.

Collectively, the many examples of possible triallelic inheritance, together with the extremely low frequencies of the identified mutations in control populations, provide overwhelming evidence in support of oligogenic inheritance in ciliopathy disorders. However, there are two cautionary notes for the clinician. First, it must be noted that it is not possible to say definitively that triallelic/oligogenic inheritance is in operation in any single family segregating three or more mutant alleles, and so this information is of limited value for genetic counseling. Secondly, the relative contribution of triallelic/oligogenic inheritance to ciliopathy disorders is likely to be relevant in only a minority (~5–8%) of families. Therefore, segregation of two mutations in a single gene is still likely to be the prevailing mode of inheritance in most patients.

## SUPPLEMENTARY DATA

Supplementary video related to this article can be found at <http://dx.doi.org/10.1016/B978-0-12-383834-6.00165-8>.

The following are the supplementary data related to this article:

**VIDEO 165-1:** Video showing a single alga (*Chlamydomonas reinhardtii*) swimming. (Reproduced from Castleman et al. (14) with permission.)

**VIDEO 165-2:** Video of the nasal pit of a live wild-type anesthetized zebra fish. Beating cilia can be seen, and flow of material within the nasal pit can also be appreciated. (Reproduced from Castleman et al. (14) with permission.)

**VIDEO 165-3:** Video of a primary nasal epithelial scraping from a normal human, showing cilia beating in a coordinated manner. (Video courtesy of Amelia Shoemark, Royal Brompton Hospital, and a still from the video is shown in Figure 165-2D.)

## ACKNOWLEDGMENTS

This work was funded by a Wellcome Trust Senior Research Fellowship in Clinical Science (P.L.B.), an EU FP7-HEALTH (241955-2-SYCILIA) grant to P.L.B., and a Wellcome Trust ViP Award (D.J.). We are grateful to Dr Hannah Mitchison for helpful discussions and data contributing to Videos 165-1 and 165-2 and Figure 165-2, to Amelia Shoemark for the data in Video 165-3 and Figure 165-2, and to Dr Paul Winyard for helpful discussions.

## Biographies

**Dagan Jenkins** is currently a postdoctoral research fellow at the UCL Institute of Child Health (2010–present). He previously completed his PhD at the same institute with Prof. Adrian Woolf (2002–2005), working on the genetics of human renal tract malformations, where he discovered *de novo* *UPK3A* mutations in patients with renal dysplasia. Dr Jenkins subsequently undertook postdoctoral training with Prof. Andrew Wilkie at the University of Oxford (2005–2010), where he discovered *RAB23* mutations in Carpenter syndrome, as well as making other contributions to the molecular genetics of human craniosynostosis. His current work uses zebra fish and mice, together with other functional approaches, to understand how *RAB23* and other cilia-related proteins regulate signal transduction, and how this modulates human disease phenotypes, including craniosynostosis and congenital heart disease.

**Philip Beales** is currently Professor of Medical and Molecular Genetics and Wellcome Trust Senior Research Fellow at the UCL Institute of Child Health. He is also honorary consultant in clinical genetics at both Great Ormond Street Hospital for Children and Guys and St Thomas' NHS Trust in London. Following general medical and pediatric training at the Royal London Hospital, he went on to specialty training in clinical and molecular genetics at Guy's Hospital. He completed a postdoctoral post at Baylor College of Medicine, Houston, Texas, following which he set up his lab at the Institute of Child Health in London. He has general interests in the genetic causes of rare diseases and childhood obesity, but has focused on delineating the etiology of Bardet–Biedl syndrome, which he co-discovered lies with dysfunctional primary cilia. He has contributed to a greater understanding of the newly emerging category of ciliopathies and the field of cilia biology, by defining a group of chondrodysplasias, including Jeune asphyxiating thoracic dystrophy, Sensenbrenner syndrome, and acrocallosal syndrome, as ciliopathies. In addition to functionally characterizing ciliopathies, his lab is now pursuing therapeutic targets for these conditions. Prof. Beales heads the Cilia Disorders Laboratory at UCL, is director of GOSGENE, theme lead for the Biomedical Research Centre and an NIHR investigator. He is an editor/board member of several journals and co-editor in Chief of the BMC open access journal, CILIA. He sits on several grant committees including the Wellcome Trust, and is a fellow of the Academy of Medical Sciences.
